

Über dieses Buch

Dies ist ein digitales Exemplar eines Buches, das seit Generationen in den Regalen der Bibliotheken aufbewahrt wurde, bevor es von Google im Rahmen eines Projekts, mit dem die Bücher dieser Welt online verfügbar gemacht werden sollen, sorgfältig gescannt wurde.

Das Buch hat das Urheberrecht überdauert und kann nun öffentlich zugänglich gemacht werden. Ein öffentlich zugängliches Buch ist ein Buch, das niemals Urheberrechten unterlag oder bei dem die Schutzfrist des Urheberrechts abgelaufen ist. Ob ein Buch öffentlich zugänglich ist, kann von Land zu Land unterschiedlich sein. Öffentlich zugängliche Bücher sind unser Tor zur Vergangenheit und stellen ein geschichtliches, kulturelles und wissenschaftliches Vermögen dar, das häufig nur schwierig zu entdecken ist.

Gebrauchsspuren, Anmerkungen und andere Randbemerkungen, die im Originalband enthalten sind, finden sich auch in dieser Datei – eine Erinnerung an die lange Reise, die das Buch vom Verleger zu einer Bibliothek und weiter zu Ihnen hinter sich gebracht hat.

Nutzungsrichtlinien

Google ist stolz, mit Bibliotheken in partnerschaftlicher Zusammenarbeit öffentlich zugängliches Material zu digitalisieren und einer breiten Masse zugänglich zu machen. Öffentlich zugängliche Bücher gehören der Öffentlichkeit, und wir sind nur ihre Hüter. Nichtsdestotrotz ist diese Arbeit kostspielig. Um diese Ressource weiterhin zur Verfügung stellen zu können, haben wir Schritte unternommen, um den Missbrauch durch kommerzielle Parteien zu verhindern. Dazu gehören technische Einschränkungen für automatisierte Abfragen.

Wir bitten Sie um Einhaltung folgender Richtlinien:

- + *Nutzung der Dateien zu nichtkommerziellen Zwecken* Wir haben Google Buchsuche für Endanwender konzipiert und möchten, dass Sie diese Dateien nur für persönliche, nichtkommerzielle Zwecke verwenden.
- + *Keine automatisierten Abfragen* Senden Sie keine automatisierten Abfragen irgendwelcher Art an das Google-System. Wenn Sie Recherchen über maschinelle Übersetzung, optische Zeichenerkennung oder andere Bereiche durchführen, in denen der Zugang zu Text in großen Mengen nützlich ist, wenden Sie sich bitte an uns. Wir fördern die Nutzung des öffentlich zugänglichen Materials für diese Zwecke und können Ihnen unter Umständen helfen.
- + *Beibehaltung von Google-Markenelementen* Das "Wasserzeichen" von Google, das Sie in jeder Datei finden, ist wichtig zur Information über dieses Projekt und hilft den Anwendern weiteres Material über Google Buchsuche zu finden. Bitte entfernen Sie das Wasserzeichen nicht.

No. 1.

NEW YORK, JANUARY, 1883.

An Address

ON THE

ANTISEPTIC TREATMENT OF DISEASES OF THE LUNGS.

*Delivered at the Inaugural Meeting of the West London
Medico-Chirurgical Society.*

By I. BURNBY YEO, M.D., F.R.C.P.,

Physician to King's College Hospital, Etc.

GENTLEMEN—When your secretary, Mr. Keetley, did me the honor of inviting me to bring before this Society the subject of the Antiseptic Treatment of Pulmonary Diseases, I confess I at first hesitated to accept that invitation. I felt that although I had given some attention to the subject, my time was at this moment so fully occupied, that I should not be able to deal with the subject so fully and completely as its importance merited, or as was due to a Society so learned and influential as yours. I also felt that it was a subject which was only just beginning to be looked at from something like a firm scientific standpoint, and that from this point of view the question of the antiseptic treatment of diseases of the lungs was in its initial stage, a stage certainly full of suggestions for future investigation, but the work of examination, of experiment, of comparison, of testing, and of criticism—serious, helpful criticism—for the most part had yet to be gone through. It might then, I thought, seem premature to introduce this subject to this Society for discussion in its present stage; but when I reflected on the intrinsic importance of the subject itself, when I thought of the vast interests, direct and collateral, involved in its discussion, and of the power and influence the members of such a Society as this would possess in collecting evidence bearing upon it, I yielded to your secretary's request, relying on your kind indulgence to excuse the merely suggestive character of this address and the many shortcomings and defects which future research alone can supply. It is remarkable when we begin to look into the history of almost any subject, how little there is that is new in its facts and its phenomena. What is new resides in our mode of regarding them, our comprehension of them, our application of them. The truth is always there in the facts and phenomena of Nature,

but it is often only discovered after ages of observation, of experiment, and of opposition. Of opposition: how remarkable is this spirit of opposition! how remarkable has it been in the history of one of the latest and greatest triumphs and discoveries in the art and science of surgery, the antiseptic system. As if the work of discovering truth in this universe was not hard enough, men are perpetually encountering from their fellow-men the most ardent opposition in this task. In proof of what I say I need only point to the present agitation on the part of a well known Society against all experiments on animals—a Society which, reversing the exclamation of the dying Goethe for "more light," might be fittingly designated "The Society for the Maintenance of Darkness."

The idea of an antiseptic treatment of pulmonary diseases is certainly *new* in our present mode of regarding it, in our comprehension of the phenomena with which it is concerned, and in the extended application which we propose to give to it. But the thing itself is not new, the phenomena are not new. The adoption and the success of antiseptic methods of treatment of pulmonary affections have been recorded again and again, and they have, again and again, met with opposition, and not rarely with a sort of sneering contempt. This, gentlemen, you may be satisfied will never be the case again, and for the following reason. Hitherto, or till quite lately, such efforts were empirical, and without any strictly scientific basis, but now our antiseptic methods are founded on scientific knowledge—on principles, principles that have been evolved from a series of most patient and at the same time most fruitful investigations, which will go far to make this latter half of the nineteenth century the most illustrious in the history of medical science. A very few historical illustrations will suffice to prove what I have said about the antiquity of the fact of the antiseptic treatment of pulmonary affections. Hippocrates and Galen used to advise the inhalation of balsamic vapors in pulmonary affections, and the latter used to recommend phthisical patients to settle in the vicinity of Vesuvius and Etna, where they could inhale sulphurous vapors as well as sea air. But we will confine ourselves to the history of pulmonary therapeutics during the last hundred years, and one of the most noticeable facts in this period is the frequency with which tar vapor has been advocated as of great value in the treatment of lung diseases. Dr. Rush, of Philadelphia, in 1787,

1883

Dr. Beddoes in this country about the same time, and Sir Alexander Crichton in 1817, all stated that they had met with great success in treating cases of phthisis by inhalation of the vapor of boiling tar, and Dr. Solis Cohen, in his excellent book on "Inhalations" in connection with this testimony, says: "The use of tar vapors in phthisis deserves to be fully and systematically studied, so that safe indications may be laid down as to the character of cases to which it is most applicable." Between 1819 and 1830 the French physicians Gannal and Cottreau, and Sir James Murray in this country, reported excellent results from the treatment of cases of phthisis with dilute chlorine vapor. One of these had noticed that the workmen in bleaching factories with chest disease visibly improved, and another reported thirteen cases of phthisis cured by inhalation of chlorine, and Louis in Paris, and Dr. Elliotson and A. T. Thompson in London, spoke well of it.

In 1835 Sir Chas. Scudamore became an enthusiastic advocate for the inhalation of iodine vapors in phthisis, and after ten years' experience of its use he expressed himself as convinced of its remedial power. Piorry (between 1850 and 1860) also was an advocate for the continuous inhalation of iodine vapor in phthisis, and for this purpose he used to have several saucers containing iodine placed about the patient's pillow. He treated thirty-one patients in this way for two years; twenty were decidedly benefited, both as regards symptoms and physical signs; in seven cases both symptoms and physical signs disappeared, and four cases died. Later still Skoda used inhalations of the vapor of turpentine with much success in phthisis, pulmonary gangrene, and in catarrhal affections of the air passages.

I have selected these few illustrations almost at random from the history of pulmonary therapeutics to prove to you that I was right in saying that there is nothing new in the facts, and they also go towards disproving the statement that I have lately seen made by one or two writers in the journals of the small amount of success that has attended the antiseptic treatment of phthisis.¹ I suppose I have as much right to speak on this subject as any of those writers, for during ten years I saw personally over 27,000 applicants in a hospital devoted to the treatment of this affection, and of all the methods of treatment of which I have had any knowledge or experience, those into which some antiseptic measure entered as an important element were certainly attended with the best results. The difficulty, however, always was to secure anything like a proper application of an antiseptic agent; and after trying various devices for this purpose, I at length devised a very simple method of continuous inhalation, which answers the purpose better than any other with which I am acquainted. I have described this elsewhere,² and you can examine the specimens of the little apparatus I have devised for this purpose that are on the table.

Let me here make a remark which as practical men you will at once see the force of. It is useless to attempt to test any method of treatment by applying it to cases of advanced phthisis. In such cases the mischief is done. No antiseptic agent will cause numerous suppurating cavities to close up and heal, or replace lung tissue that has been destroyed by progressive ulceration and disintegration, or remove extensively disseminated tubercular and inflammatory infiltrations. And yet how many cases of phthisis come before us already in

this state. It is greatly to be regretted that certain physicians should ever have pretended to have cured such cases, and that others should seriously have tested their statements by the application of any special method of treatment to cases so advanced and so hopeless. In order that any case may be cured by any method of treatment the first and essential condition is that it should be curable. And cases of phthisis too often come for the first time under our observation long after the possibility of cure is passed. But the question for us to examine and to satisfy ourselves about now is this, Is an antiseptic system of treatment applied to lung diseases true in principle? If we can convince ourselves that the principle is a true one, modes of application and developments in practice will be certain to follow. In the first place, then, let us inquire, What is antiseptic treatment? Antiseptic treatment applied to the lungs is one or both of two things: First, it is the prevention of a hurtful, poisonous (septic) agent getting to the lungs from without; and, secondly, it is the destruction, or the limitation of the action of a hurtful poisonous (septic) agent already within them.

And now let us ask ourselves if there is any *a priori* reason why it should not be possible to satisfy both these indications. It was argued warmly not many years ago, as a necessary preliminary to this discussion, that it was impossible to bring medicinal agents into contact with the pulmonary surface by inhalation. That argument has been abundantly disproved by the most varied and elaborate experimental investigations.³

So, then, supposing a hurtful septic agent to exist in the lungs—and in phthisis the presence of such an agent has been demonstrated beyond all question, and its virulently septic quality established—the problem of the antiseptic treatment is this: Do we possess, or can we discover, any agent which we can convey, in the form of gas, vapor, or solution into the lungs which shall be inimical to the life and activity of this septic body? Or can we place our patient under any possible conditions of life which shall prove hostile to its growth and development? It would be illogical and absurd in the extreme to deny the possibility of such a method, or of the discovery of such an antiseptic agent, if we do not already possess one or more. The second indication must therefore be admitted to be quite possible. Now, let us turn to the first indication. It is not only necessary to destroy any septic agent that may be already in the lungs, but we must be able to prevent septic agents from entering them with the respired air. Now, this may be accomplished in two ways: (1) We may place our patient in an atmosphere which by examination we know to be absolutely pure and free from septic particles; or (2) we may diffuse through the air he breathes an agent hostile to the life and activity of any septic particles there may be in it. This, again, is a true antiseptic treatment, and it is certainly possible in either of these two forms. If then we limit ourselves (which we had better do on this occasion) to the consideration of the treatment of phthisis, we have two things satisfactorily proved. First, there does exist a hurtful specific septic agent in the lungs. Second, an antiseptic treatment is possible. There is no beating the air in this. Gentlemen, we are here on sure and certain footing; we have reached a principle. This is only the first stone of the edifice we have to build, but it is the foundation stone. The next thing for us to do is, by patient labor in the way of observation and experiment, to apply this principle. Our object is to discover what agents there may be within our reach capable of being administered

¹ In my recently published Lectures on Consumption I have collected a mass of contemporary testimony in favor of this treatment.

² Lectures on Consumption. London: J. & A. Churchill.

³ Vide Oertel: Respirator schen Therapie.

without inflicting injury to the pulmonary tissues, which may have the power of destroying, or neutralizing, or arresting the activity of the septic organism, which seems to be the operative cause in the origin and propagation of phthisis. I am disposed to believe that other common forms of disease of the respiratory organs have a septic origin also, and call for antiseptic treatment, but we must for the present concentrate our attention on this subject of phthisis.

Already we have abundant and incontestable proof that pure air—pure, cool dry air, in unlimited amount—is such an antiseptic agent. Wherever such air is found—on the high tableland of Mexico, in the elevated valleys of Switzerland, on the Kirghiz steppes of Asiatic Russia, in the pine forests of Central Germany, and on the open sea—wherever men live a life in the open air, away from the emanations of cities, and from too close contact with humanity,—in all such places we hear of consumption becoming arrested and cured. The bacillus tuberculosis seems to love hot, moist air, and air freely charged with the exhalations of humanity; warmth and moisture seem to provoke it into special activity, while dry air at a comparatively low temperature seems to be inimical to it. Whoever has watched, as I have done, a large number of cases of phthisis in this country, must have been struck with the frequent occurrence of rapid advances in the disease during the first warm moist days of spring and early summer.

And here again I am tempted to quote a passage to which my attention has been recently called by my friend, Dr. Frank, of Cannes, to show how true it is that the facts we are discussing are not new. It occurs in a very able book by a German writer, "Hausrath on New Testament Times," an English translation of which has been published by Williams & Norgate. He is alluding to the mountain air of the fortress of Masada, a mountain fortress on the borders of the Dead Sea, where John the Baptist was imprisoned. There, he says, Josephus tells us provisions retained their freshness for over 100 years "because the air at the altitude of the fortress was purified from all earthly and corrupt particles!" It is precisely such air—air purified from all "corrupt particles"—that we require for our phthisical patients; and if we cannot send them where such air is naturally found, we must artificially create for them an antiseptic atmosphere which they can breathe where they are; and if we are to perpetuate consumption hospitals, it is with such an atmosphere we must fill them. But the time will probably come when instead of crowding a number of consumptive patients together in the centre of a populous district of a crowded city, we shall acquire for the same purpose a good-sized pine wood with a dry subsoil a few hundred feet above the sea-level, and build a certain number of scattered cottages through the wood, and hang up a number of hammocks between the fir trees and send our consumptive patients there to be aired into health! In wet weather they would make up fires of fir wood and pine cones, and so fill their cottages with balsamic and antiseptic vapors; and with open windows and a dry soil they would find the wet weather less injurious to them there than in towns. But we have other antiseptic resources more manageable than a pine wood. And here let me call your attention to the peculiar anatomical conditions of the respiratory organs, by which they are rendered peculiarly prone to septic attack, and specially needing of antiseptic defence. The lung is the only deep-seated internal organ in the body which is freely accessible to the surrounding air. Perpetually the outer air is passing in and out of the

lung, and thus septic particles in the air can readily reach the pulmonary surface, which is most richly supplied with absorbent vessels. But if, owing to the anatomical disposition of the parts of the lung septic bodies can readily reach it from without, for the same reason antiseptic particles can also be readily brought into contact with it, either in the form of gas, or vapor, or fine spray and mist, or even fine solid particles.

It is needless to offer you any proof of this. You will, I take it, all accept this statement as proved; and you are no doubt familiar with various forms of apparatus devised for the purpose of carrying out such applications. But though we may sterilize or destroy in this way such germs or microbes as may commonly occur in the surrounding atmosphere, and so purify and render harmless the air that passes in and out of the lungs in respiration, it does not follow that the agents we now know to be germicides, such as carbolic acid, eucalyptol, thymol, etc., and which are used by surgeons on account of that property, are necessarily destructive of the tubercle bacillus. Analogy would lead us to conclude they might be, and the experience of their use in the hands of many competent observers,* tends to strengthen this view. But we must not rest satisfied with this; we must pursue our studies of the life-history of the tubercle bacillus until we have discovered what is the particular agent or agents which are especially inimical to its development and activity.

There is another difficulty which we must be prepared to encounter—the difficulty of inducing patients to submit to a continuous process of disinfection. It is by no means easy to induce phthisical patients to wear, almost continuously, even so light and simple an appliance as the one I have shown you, and it would be infinitely more difficult to get them to inhale a spray for many hours a day, supposing it should be discovered that the best antiseptic is soluble in water but not vaporizable at ordinary temperatures, as was the case with the benzoate of soda of which so much was expected by some. But I believe this difficulty would almost entirely disappear if our knowledge became absolutely precise, and our confidence in our remedy completely assured. If we could say to our patients "by this means you will be cured, and by no other," this difficulty would, I am persuaded, almost cease to exist. Hence, however, we see the obvious advantage of being able to remove our patients to an antiseptic atmosphere where they cannot help inhaling the curative agent continuously.

And now I must bring these merely suggestive observations to a close. In the foregoing remarks I have chiefly endeavored to show that the idea of an antiseptic treatment of lung diseases is based on scientific data, and that in principle it is established as a truth. What lies before us is to overcome the difficulties in its application. We should be encouraged in this work by the thought that whatever progress we are enabled to make we shall be furthering the labors of the great experimental pathologists of our times, the labors of men like Pasteur, Koch, and Lister. It is not given to everyone to be enabled to work with a genius and an energy like theirs. But let me remind you that one of them—Koch—was a country doctor, a general practitioner, like many who are here to-night; and we may all do something towards transferring the influence of their intelligence and their genius, and in applying the fruits of their labors to the practical daily duty of healing the sick; and in spite of much disingenuous misinterpretation and foolish abuse we may be able to prove to the world

that experimental pathology is in the very highest degree beneficent and philanthropic. For the first time we seem to have grasped a principle in the treatment, both preventive and curative, of a class of diseases which we have hitherto regarded almost with despair. Let us steadily work on the foundation which this principle supplies, the successful application of which must be attended with immense service to humanity and lasting honor to medical science.

Clinical Lecture

on

TUMOURS.

Delivered in the Liverpool Royal Infirmary, July 26th, 1882,

By **RUSHTON PARKER, B.S., F.R.C.S.,**

Professor of Surgery in University College, Liverpool.

THE word "tumour" is familiar throughout the scientific world. In English, French, and Italian the spelling differs only by a letter or two from that of the Latin "tumor," which is preserved unchanged in Spanish and by a large proportion of English-speaking persons. A tumour is a swelling or lump, and these three names are applied, in medical practice, to morbid conditions in which increase of size is a feature. Every enlargement is accordingly a tumour, which, on complete investigation, will invariably be found to be one of the following things:—

1. A *distortion* or *displacement*: as in a hernia, a fractured or dislocated bone, ruptured muscle or other organ, and in some congenital deformities. A *distension*: as an over-filled bladder, intestines, etc.; an aneurism, a varix, a hydrocele. In some such sense a hematoma or blood extravasation must often be considered.

5. An *obvious inflammation*: as in abscess, especially chronic; in rheumatic enlargement of bones, and other indurations.

3. A *local hypertrophy*: as in congenital enlarged toes or foot, congenital moles of the skin, elephantiasis, hyperostosis (?).

4. A *tumour proper*.

Though every tumour necessarily falls into one of the above four categories, it is by no means always easy, or even possible, to be certain which that category is. For various reasons, the many elaborate definitions that have been devised with the view of representing exclusively those new formations or neoplasms that are reckoned among tumours proper are unnecessary, since every specimen in the above list of morbid conditions is confessedly called a tumour in practice, both before and after recognition. They are, moreover, useless, since not one of these definitions successfully describes the fourth group in language that invariably excludes the other three.

1. In the first class a hernia, a dislocation, or an over-distended bladder are capable of certain distinction from tumours proper. Yet a hydrocele of the tunica vaginalis or spermatic cord is a pathological effusion of fluid into a cyst that should be empty or absent. Is it an accidental physiological "distension" of Class 1, or is it a well-ascertained "inflammation" of Class 2; or is it without ascertainable cause, and a form of cystic "tumour proper" of Class 4? Again, an atheromatous sebaceous tumour is physiologically due to retention and accumulation of sebaceous secretion, closing, over-distending, and thickening a cutaneous gland,

converting it into a more or less globular cyst. It is confessedly regarded as a cystic variety of tumour proper; yet its causal resemblance to hydrocele is very close, and the distinction of either from an overfilled urinary bladder is one of degree rather than of kind.

2. Among "obvious inflammations," a chronic abscess and a glandular enlargement are capable of a recognition, that if not clinically easy or immediate is ultimately certain on dissection. A fluid distension of a patellar or other bursa is a purely inflammatory phenomenon, which subsides on the application of suitable treatment, with or without previous evacuation; yet a fibrous thickening of the same bursa, though equally of inflammatory origin, may fail to disappear on the removal of irritation. There is something of the nature of "hypertrophy" in the increase of fibre-growth or production; though for all essential purposes it is called a tumour proper. Yet the clinical features and many of the pathological phenomena of certain tumours called malignant partake so strongly of the inflammatory type as to call for detailed comparison presently under the proper head.

3. Enlargement of bone, the obvious effect of inflammation, and similar enlargements called hypertrophy or hyperostosis, are constantly and inseparably blended with bony "tumours proper," from which they cannot always be distinguished, and with which they must often be identified. Is a pedunculated exostosis, produced by acrogenous ossification of its cartilaginous tip, an instance of "displacement," in the period of growth, of a fragment of epiphyseal ossifying cartilage? Is it an example, in addition, of "hypertrophy" of cartilage, of bone, or of both? or is it, when finished, a "tumour proper," whether as a pedunculated exostosis, or as a great "enchondroma" with so proportionally inconsiderable a bony pedicle as hardly to suggest its similar origin and mode of growth? Who is to say? Except obvious inflammation, all the above categories may claim it.

4. Tumours proper are of many kinds, and must be classified for systematic discrimination, and for the mutual assistance of observers. Such arrangement as may be from time to time adopted for this purpose depends upon a variety of considerations, summed up in the purport and ultimate result of a tumour in its natural course, or in that modified by interference. Some tumours give little or no inconvenience, being harmless excrescences when situated in parts ordinarily concealed by the clothing, or, if exposed, being at worst unsightly. Others that may be painless are inconvenient deformities, whether concealed or exposed, attaining an excessive size and weight, the physical incubus of which is scarcely mitigated by an associated slowness of growth. But pain, though generally, is not always absent from otherwise non-injurious tumours, and those that are painful happen to be usually small and sometimes diminutive, not seldom suggesting, from their situation in or beneath the skin, the probable entanglement of nervous filaments. The situation of an otherwise harmless growth, as, for instance, beneath the tongue, in the orbit, or displacing the windpipe, may imperatively demand its removal. Finally, the skin over an innocent tumour now and then becomes ulcerated, with risk or loss to life through hæmorrhage or blood-poisoning. Such catastrophes are but indirectly associated with the morbid growth, and are, in fact, more or less accidental complications, which may accordingly be avoided.

These, then, are the attributes of benignancy, as contrasted with those of malignancy, next to be considered. All tumours proper are either benignant or malignant. The former are local

abnormalities that have no inherent tendency to endanger life, and frequently fail to inconvenience their possessor; while the latter, though occasionally perfectly curable by operative removal, are always dangerous, and, though often temporarily checked with the effect of prolonging life, are only too frequently rapidly or hopelessly fatal. The size of a malignant tumour may be little or no guide to its nature, or measure of its danger. Rapidity of growth, however, is an almost constant feature, rendering them all conspicuous, and giving to their proportions, if at all huge, a significance that is something appalling. There is a special inveteracy in their growth, evinced in varying degrees and modes—(a) Ulceration of the integuments, over malignant growths, is a conspicuous though not invariable feature. The attendant exhausting complications, blood-poisoning, hæmorrhage, and pain, though often as adventitious as in their more exceptional occurrence in the benign, assume by their frequency quite an integral importance. (b) A liability to reappear near the seat of removal, even after what has seemed to be thorough excision; suggesting the neighboring existence of infective particles which, though undiscovered by the naked eye and microscope alike, are still suspected to imbue the tissues or fluids. (c) An infective spread to, and inveterate infiltration of, the lymphatic glands pertaining to, and draining, the seat of primary growth. (d) A dissemination in viscera, serous membranes, or subcutaneous and interstitial connective tissues, of tumours identical in most particulars with a primary original growth, which latter, though almost invariably obvious, occasionally eludes discovery. These disseminations are believed to be embolic, the infective particles being conveyed in the blood-stream and lodged in the arterial or capillary system, growing into tumours after their arrest. Some evidence is circumstantially furnished in the form of thrombi, composed of the tissue of malignant tumours, that are sometimes found filling neighboring veins of various sizes visible to the naked eye, and that may be often presumed to similarly invade smaller veins that are not thus visible. Microscopic investigation has, moreover, revealed the actual presence of malignant emboli impacted in minute afferent blood-vessels of viscera; proving to demonstration both the fact of conveyance and its mechanism.

Now, ulcerated swellings of the lip or tongue, the face or cheek, skin, or mucous membrane, due to cancerous invasion, to syphilitic infection, or to non-specific inflammatory induration, have resemblances conspicuous and puzzling to all, sometimes temporarily misleading the ripest experiences, and therefore undeniably real. The clinical import, various in name and in course, is eventually clear in most instances, but the anatomical comparison, pushed to its furthest histological limits, not merely confirms the characteristics of divergence, but clenches the identity in points of resemblance. A simple inflammatory induration subsides on the discontinuance of the physical irritative cause, a specific infection of syphilitic influence as truly disappears by exactly similar means, or by the organic administration of a constitutional chemical antidote or by both. The physiological aberration in simple inflammation, due to the irritation of mechanical agency, is reproduced in the infective forms, where the irritative effects of a specific virus, as a parasitic organism, when known at all, are chemically and otherwise manifested. Such are the exudations of præmia, of syphilis, of tubercle. The visible products of malignant disease suggest comparison with those of infective inflammation. They are more luxuriant than the simple inflammations, but

incapable of undergoing absorptive resolutions on the removal of irritation. They are exempt from suppuration, except, apparently, in the added complication of putrid irritation, but are amenable to no ascertained system of antidotal medication, and share with tubercle the necessity of removal as the sole accessible means of practical cure. They appear, especially in the case of some sarcomata, to partly owe their commencement, mysteriously, but almost undeniably, to the operation of local injury, in which respect "acute traumatic malignancy" resembles infective inflammation, such as acute necrosis and, perhaps, caseous tubercle of bone. In anatomical structure malignant tumours conform largely, and often strictly, with inflammatory type; in superficial features, in physiological infection, and in much of their clinical inveteracy, they resemble products of known parasitic agency. There lacks only the discovery of a visible parasite to complete the analogy.

Classification of Tumours proper.

Accumulated observations of the external appearances, general behavior of tumours, their localities, physiological development and anatomical structure have resulted in attempts at classification, truly reputable in their day, but necessarily changing with the advance of knowledge, and proving eventually more or less unsatisfactory in phraseology, if not in fact. The diseases remain the same if their names have been changed, though by fresh discoveries they seem sometimes to be multiplied, at others to be reduced in number. Some of the names, too, have undergone changes of meaning; so former terms and their previous significations must be noticed for purposes of interpretation. Among benign tumours the names explain themselves and their possible synonyms; it is in a portion of the malignant series that confusion has arisen. The classification of tumours according to their anatomical structure, associated with the name and times of John Abernethy, was a memorable step in naked-eye procedure. The refinements of the same principle, effected in the microscopic era, have celebrated the name of Virchow and of his contemporaries at home and abroad. The resolute appreciation of all clinical features, and a refusal even to admit anatomical distinctions except in subordination to the former, are at once most conspicuous characteristics of the example and teaching of Billroth, and a tribute to all that is excellent in cultivated empiricism. By employing two methods of classification in alliance, instead of preferring or excluding either, there has latterly resulted a systematic arrangement of all tumours proper, the malignant apart from the benign, assorted in anatomical sequence. The best statement of this kind is probably that which appeared in 1877, in the seventh edition of Erichsen's Surgery, found also in all essential outlines in the subsequent edition of Green's Pathology, and of Holmes' smaller work. The following table is prepared; with slight alterations, from Erichsen's account.

Benign tumours are divided into—

I. Cystic tumours in general.

(1) retention cysts.

A. In glands or their ducts,

Cutaneous (sebaceous), as wens or atheromatous tumours, including "horns."

Mucous (mouth, vagina, etc.):

Glands of Bartholin—Cysts of vulva.

Glands of Cowper—Male perineal cysts.

- Larger glands.
Salivary—Ranula.
Mammary—Simple cysts
- B. In ductless glands or cavities.
Bursæ—Hydrocele, housemaid's knee, bunion.
Sheaths of tendons, ganglion—Liquid, fibrinous, fibrous.
Ovary or thyroid glands—Simple cysts.
- (2) Newly formed closed cysts.
- A. Dermoid, congenital tumours.
(a) Sebaceous, placed away from seat of sebaceous glands.
(b) Ditto, with wall of true skin structures, glands, hair, etc.
(c) containing teeth, bone.
- B. Serous, simple cysts.
Congenital, as hydrocele of neck or shoulder.
Arising in solid tumours.
- C. Proliferous, compound cysts, of ovary and elsewhere.
- D. Blood-cysts—Hæmatoma, hæmatocele.
(The same occurring in solid tumours.)
- E. Parasitic cysts—Hydatids.
- II. Tumours composed of one of the modifications of fully developed connective tissue.
- Fat—Lipoma.
Fibrous tissue—Fibroma.
Mucous tissue, like that of umbilical cord or vitreous humor—Myxoma.
Cartilage—Chondroma, enchondroma.
Bone—Osteoma, exostosis.
Tooth—Odontoma.

III. Tumours which resemble in structure, more or less perfectly, one of the more complex tissues of the body.

- Muscle—Myoma, myofibroma, as in uterus prostate, etc.
Nerve—True neuroma.
Blood-vessels—Angioma, nævus, also called cavernous or erectile tumours.
Lymph-vessels—Lymphangioma.
Lymph-glands—Lymphadenoma.
Papillæ (of skin or mucous membrane)—Papilloma or wart.
Secreting glands—Adenoma.

A. Myeloid tumours of bone (*see* Sarcomas).

Malignant tumours are divided into—

IV. Sarcomas, or tumours composed of tissue which is either purely embryonic, or is undergoing one of the primary modifications seen in the development of adult connective tissue. Arising in connective-tissue layers and interstitial spaces, such as fasciæ, periosteum, bone, marrow, adipose tissue, corium, submucous tissue, the framework of secreting glands, and lymph glands.

Present names.	Older names.
A. Myeloid or giant-celled sarcoma. (This variety alone is non-malignant.)	Myeloid, fibro-plastic tumours (in some cases).
B. Spindle-celled sarcoma. Fasciculated sarcoma.	Fibro-plastic tumour (as generally understood). Recurring fibroid.
B*. Spindle-celled melanoma.	Melanosis, melanotic cancer, fungus hæmatodes.
Or Melanotic Or Pigmented	Spin. celled sarcoma.

Present names.	Older names.
C. Round-celled sarcoma. Alveolar sarcoma. Fibro-sarcoma. Lympho-sarcoma, and malignant lymphadenoma.	Encephaloid cancer. Medullary sarcoma or cancer.
Round-celled melanoma.	Melanosis, melanotic cancer, fungus hæmatodes.
Melanotic Pigmented	Round-celled sarcoma. Alveolar sarcoma.
Myxosarcoma.	Probably often called colloid cancer.

V. Carcinomas, or tumours composed of cells of an epithelial type, arranged in spaces in a stroma consisting of more or less perfectly developed fibrous tissue. Arising in and consisting largely of cutaneous, mucous, or glandular epithelium.

- A. Cutaneous epithelioma of skin.
Cutaneous epithelioma of lip, anus, etc.
Cutaneous epithelioma of prepuce, glans penis, vulva, etc.
- B. Mucous epithelioma of tongue, gums, mouth, fauces, gullet.
Mucous epithelioma of stomach, intestine.
- C. Glandular cancer of breast, pancreas, and other glands.

Sarcomas of Bone.

Any of the malignant sarcomas may arise in the fibrous covering of bones, their names being then preceded by the additional word "periosteal." Or they may arise in the central fat, whether of cancelli or of tubular marrow. In any of these central tumours may be found giant-cells or myeloplques; sometimes so abundantly as to give the growth a resemblance to ordinary myeloid, microscopically, though differing in all other respects. The following sarcomas are peculiar to bone, and may be of either central or periosteal origin: osteoid chondrosarcoma, osteo-sarcoma or ossifying sarcoma, both otherwise known as osteoid cancer. Carcinoma never arises primarily in any bone, but invades it secondarily either by contiguous spread from another primary source (as skin, tongue, mammary gland, etc.); or as a reproduction by distant conveyance in the circulating fluids.

Mammary Tumours.

I. Benign.

(a) Cysts.

- | | |
|---|--|
| (1) Simple. | Unilocular.
Multilocular. |
| (2) Adenocoeles.
Cystic adenofibroma.
Cystic adenomyxoma.
Cystic adenocarcinoma. | Other names:
Chronic mammary tumours, serocystic tumours. |
| (3) Parasitic hydatids (rare). | |
| (b) Simple tissue tumours (rare curiosities).
Lipoma, chondroma, osteoma. | |
| (c) Adenomas, and pure hypertrophies. | |
| (1) Non-cystic adenofibroma of young women. | |
| (2) Simple general hypertrophy. | |
| (3) Simple local hypertrophy.
Acinous adenoma.
Tubular adenoma. | |

II. Malignant.

(d) Sarcomas.

Round-celled sarcoma.	Known formerly as fungus hematodes, pulpy medullary sarcoma, fibroplastic tumours, and some cases of so-called encephaloid cancer.
Spindle-celled sarcoma.	
Myxosarcoma.	
Alveolar melanoma.	
Alveolar giant-celled sarcoma.	

(The rare varieties observed by Billroth)

(e) Carcinomas.

Anatomical varieties, now classed by Billroth, as—

(1) Acinous cancer.	Variously known as scirrhus and medullary, or encephaloid cancer.
(2) Tubular cancer.	
(3) Shrinking cancer.	
(4) Gelatinous cancer.	Colloid cancer.

As to the causes of tumours proper, many of them among the benign are known to be either congenital or developmental excrescences, as for instance—1. Dermoid and other congenital cysts in the permanent or temporary orifices, or in the cavities and organs of the body. 2. Pedunculated cartilaginous exostosis. 3. All nævi, warty and pigmented cutaneous moles. But a notion has arisen, and has been treated of by Cohnheim, that tumours have their origin in portions of embryonic tissue lying in the numerous interstices of the body, and undergoing the developmental alterations necessary to produce them; a form of growth which, in the case of simple solid tumours, is a mere repetition of that which occurred in the completed tissues which they imitate or exactly resemble. This notion has been so far supported by experiment that fragments of embryonic cartilage, transplanted to the aqueous chamber of the eye, to the peritoneal cavity, and into the stream in the jugular vein, have grown into cartilaginous tumours, whereas fragments of completed periosteum and hyaline cartilage, similarly dealt with, grew only for a time, and eventually underwent absorption. The notion, though quite as yet unproved, is interesting, if not important, affording a credible and comprehensible mode of accounting not only for all solid and some cystic benign tumours, but possibly malignant too, for, when considered along with a supposed anatomical alliance with inflammation of a possibly infective type, and with the strongly suspected "traumatic" excitation of "malignancy," one or other, and sometimes all, of these hypothetical explanations may be applicable to the origin of the groups sarcoma and carcinoma in completion of the idea. In fact, evidence is not wanting in support of some such idea in the case of certain instances of "branchial carcinoma" related by Volkmann (*Centralblatt f. Chir.*, Jan. 28th, 1882). This term he has applied to examples of deep, primary carcinoma of a distinctly cutaneous epithelial composition, excised by him from the stylo-hyoid region, and supposed to have arisen in epidermic structures included at the obliteration of the branchial clefts¹. Among the tumours of the breast preserved in this museum is one (F. 30) of cystic nature, excised with the whole gland. The

soft contents had the naked-eye appearance which characterizes some softened epitheliomatous swellings, especially when secondarily affecting lymph glands, and the cyst wall was found by Mr. Paul to show the microscopic structure of unmistakable cutaneous epithelioma, an opinion which I entirely confirm from inspection of the slides. Such a product is extremely uncommon if not as yet unique, and not accounted for on any plan that has yet been devised to explain the origin of tumours, except the one now referred to. One may imagine a congenital or developmental aberration of cutaneous tissue, such as might form a small subcutaneous or even intra-mammary "dermoid cyst," however minute, subsequently undergoing the same transformation into epithelioma that any previously healthy cutaneous part would have to undergo when invaded by this disease. The same may apply to sarcomas, and may account for their hitherto mysterious appearance in the numerous connective tissues and interstitial spaces of the body. Their relation to congenital structures is so far known that a cutaneous pigmented mole may in after life be the actual and only seat of sarcomatous infiltration. Such a specimen is mounted in this museum. It is said that, under circumstances such as these, the usual malignant course is not manifested, though the structure be identical with that seldom unattended otherwise by recurrence, infection, and fatality.

Introductory Lecture

TO THE

COURSE OF SURGERY

IN THE

UNIVERSITY OF EDINBURGH.

Delivered Oct. 24th, 1882.

By JOHN CHIENE, M.D. Edin.,
Professor of Surgery.

THE Chair of Systematic Surgery in the University of Edinburgh is of comparatively recent foundation. The cause of this is not far to seek. For many years it was held conjointly with the Chair of Anatomy. As the range of anatomical science increased in scope and importance, and when in 1736 the foundation of the Royal Infirmary by the Royal College of Physicians brought more prominently forward the practical aspects of surgical teaching, it was evident that the double work was too great for any one man. The Royal College of Surgeons early recognized this necessity, and in the interests of surgical science they petitioned the patrons in 1777 to found a separate chair. It was not, however, till the year 1831 that a Chair of Surgery was founded, and J. W. Turner was elected professor of surgery. He was succeeded in 1836 by the great physiologist and scientific surgeon, Charles Bell. He, in his turn, was succeeded in 1842 by James Miller; and on his death in 1864, James Spence, whose loss we now mourn, became professor of surgery. I well remember Mr. Spence's introductory lecture, delivered in this class-room eighteen years ago, before a crowded audience of students, former pupils, and friends: his leading thought—the gradual growth of surgical science; his subject—the Edinburgh School of Surgery. He laid special stress on the influence of John Bell and Robert Liston. Of John Bell he says, "He was no ordinary man, but a real surgical genius, of great natural talents, and imbued with that enthusiasm which is a mark

¹ I have also met with one case of this kind, and have the microscopic slides prepared from a deep primary cutaneous epithelioma, removed some years ago from the left side of a middle-aged man's neck by Mr. J. P. Harris, assisted by me. The thing had puzzled me until I saw Volkmann's paper.

of genius, and which does so much to create enthusiasm in others." Of Liston he says, "As a bold, and cool, and dexterous operator, I have scarcely seen his equal. His great power in diagnosis, the wonderful faculty he possessed of perceiving, as if by intuition, the true nature of a case in all its bearings, and of adopting adequate measures for its treatment was such as are rarely to be met with." Syme and Fergusson were then alive, and the time had not yet come to form an estimate of their great power for good. William Fergusson had gone to London, and was at that time at the height of his fame as a skilful surgeon, a brilliant operator, and, above all, a kind friend and adviser to anyone from Scotland. Of this I have a very pleasant recollection, when, in 1867, he gave me sound advice in what was probably the turning point of my career, advising me to stay in Edinburgh, and not to migrate south as so many of my countrymen had done. He never forgot the land of his birth. James Syme was then the leader of Scottish surgery, of whom it might truly be said in the words of that good kindly man, the author of "Rab and his Friends," "He was, I believe, the greatest surgeon Scotland ever produced." "He had that quality of primary minds of attaching permanently those he had relation to, his students never ceased to love him, and returned to him from all regions of the world." As one of his pupils may I be permitted, in John Brown's words, to say, "Of what he was to me—his patience, his affection, his trust, his wisdom, and still more, what he might have been to me had I made the most of him—it is not for me now to speak. He remains in my mind as one of the strongest, clearest, capablest, most valuable understandings; one of the warmest, truest hearts I have had the privilege and the responsibility of knowing." It has often been a matter of surprise to me that Syme's works have never been re-issued in a collected form. They will always be classical. I feel sure of this that there are many of his old pupils who would gladly undertake the task. Mr. Spence, in his introductory lecture, pointed out to us, his students, the great importance of anatomy and clinical study, of the dissecting-room and the hospital ward. He could speak with authority on these points, because he had been for many years a teacher of anatomy, and for fifteen years a surgeon in the hospital and lecturer on surgery in the extra-mural school. When we remember that Charles Bell held the Chair of Surgery in this university, physiology must always play an important part in the surgical teaching. With our vivid recollection of the complete mastery James Spence had over all the details of anatomy, we can never forget the paramount importance of anatomical dissection as the basis of surgical practice.

As many of you know, it has been my endeavor, during the last twelve years, to teach the principles of surgery from a physiological standpoint, the practice of surgery from an anatomical point of view. While I certainly shall have difficulties as to the best way fully to utilize and develop the great opportunities for good which my present position affords, one thing I feel sure of is this, that in the future there will be no necessity for any departure from the method of teaching that I have always hitherto followed. I shall be encouraged, in so doing, by the remembrance that I hold a position previously occupied by Charles Bell and James Spence. It was my good fortune to be the pupil both of James Miller and James Spence. Miller, an eloquent lecturer, a brilliant operator, and a kind-hearted man; Spence, the representative, for some years before his death, of Scottish surgery, the careful and painstaking surgeon, whose skill as a diagnostic surgeon was unrivalled. You know

how well he did his work as your professor; he never forgot—what has ever seemed to me the reason why Edinburgh attracts so many students—that teaching was his primary duty. His daily lecture, his hospital visit, were to him a time sacred to learning and teaching, and not to be lightly interfered with by the calls of practice, however urgent. You know how hard he worked; of late the troubles of declining years interfering in no way with that thoroughness in all he did, and that daily round of arduous duties the performance of which was to him his chief pleasure and his life-work. I would desire to remind you of his avoidance of all show. I recall at the present moment the early days of the winter session of 1862, the operating theatre in the Old Infirmary, Spence evidently pre-occupied, restless, and excusing his restlessness by an occasional glance at the instrument-tray, as if every knife and every needle had not been carefully examined and arranged by himself; the theatre crowded to the ceiling, a small sprinkling of practitioners amongst a host of students. The juniors, of whom I was one, were somewhat anxious, and perhaps not over-confident of their staying powers; the seniors, who had left the medical house to visit their old haunts and see "Spence operate," were there in great force, some perhaps thinking of the time when they were juniors, with heart-searchings of time misspent, never to be recalled, others in whispered comments recalling some dreadful operation which they had witnessed, patronizing, but withal in a kindly fatherly manner, us juniors. The patient was soon brought in, a pale but healthy middle-aged woman. She suffered from a large tumour of the neck. I need not detain you with an account of the operation; the time seemed to me short—it must have occupied an hour. During all that time Spence went on with his work quietly; little was said, but gradually the large growth, separated from its attachments, became more and more apparent, until at last it was removed, and a gap was left, exposing the carotid vessels and the internal jugular vein from the angle of the jaw to the clavicle. That large blue vein is still vividly before me. I remember my only thought was, that man must be a good anatomist. This was my first lesson from James Spence; since that day it has been my great privilege to receive from him very many practical lessons and much kindness. It will be an evil day for the teaching of surgery in this school when the useful lessons which Spence taught are forgotten by his pupils. He was a good practical surgeon, a kind friend, and an honest man. In his "Lectures on Surgery" he has left us a guide which will always be eminently trustworthy, more especially in those branches of practical surgery to which he devoted special attention. His chapters on hernia, aneurism, diphtheria, croup, stone in the bladder, their diagnosis and treatment, are to my mind full of sound advice, and will always be read and acted upon, and Spence's name will be handed down as an authority in practical surgery.

The term "introductory" may refer either to the lecturer or to his subject. Personally I am pleased to feel that I require no formal introduction. May I then be permitted to utilize what remains of this hour, and make it a part of the course on which we are now entering? I have no desire that this lecture should in any sense be of the nature of a pastime, but that to-day, as I trust in every lecture this session, something will be learned by you and by me. To be useful, what I have to say must be more or less elementary; for this I cannot but feel that I owe an apology to those present, old friends and former pupils, who come here to welcome me in a new position, and to other kindly critics present, who have perhaps finished or are

now finishing their university course. While my remarks are more especially addressed to students of the second year who are commencing the study of surgery, I am well aware that there are some present fresh from school life who are only now beginning their medical studies, and who as yet consider it a privilege to attend an introductory lecture, and who can still enjoy their comparative freedom as university students, comparing it favorably with the rigor of school discipline with which very lately they were so well acquainted. May I as a friend say to them a passing word? In your present freedom there is a great danger: see that you use that freedom aright. Remember that you are now university men. Your school looks to you to be a credit to your up-bringing; your university hopes in the future to be proud of you. Take this to heart, that your future prosperity very much depends on the way you spend your first year here. I earnestly entreat you to take great care what friends you now make. You will most certainly be tempted. Learn then, above all things, to be able to say "No;" that is the whole business, and I have no fear of the result. "Read carefully; do not be satisfied with a superficial understanding of a book, nor hastily give your assent to those who talk too much."

Pardon me for this short digression; I could not help it. I have seen in my day many bright beginnings end only in disaster, self-reproach, and home misery. My audience is a large one; perhaps what I have now said may be of use to some one junior student now present.

The healing of wounds has from the beginning occupied the attention of surgeons. Rapidity of healing and freedom from pain during the process have mainly been sought after in their treatment. In saying a few words regarding wounds, I would first direct your attention to the treatment of a wound twenty years ago, when I was a student, comparing it with its treatment at the present time. I necessarily, in my comparison, take the practice of the school with which I am most familiar. Its practice, however, has always been a pretty good gauge of the work of practical surgeons. I do not wish to say that it has been foremost, but certainly it has always been among the first to institute or adopt any improvements. Twenty years ago, as at present, there were differences of opinion in minutiae, but the practice of the majority at this period will be taken as the basis of our comparison. I will have no difficulty in showing that most remarkable alterations have taken place; and I will then ask you to look into the past history of surgery, and I think be able to show you that the present practice has been more than foreshadowed, and that much that is now done has been done long ago. In some minds there seems a tendency to dwell upon the so-called ignorance of our forefathers. I would assert the very opposite, and say that there were clear-headed, shrewd, and intelligent surgeons in those days who can most favorably be compared with the present generation. This assertion, if just, is a comforting one, and may encourage us to hope that any honest, truthful work that is now being done will be appreciated by our successors. If then I can show that the present practice of surgery is a revival of what was done in the past, it will be my endeavor in the next place to point out the real difference, and to show that, while surgeons formerly worked empirically, we are now working on a scientific basis.

The present practice and its results on general surgery will occupy our attention during the coming session. While I have no desire to prophecy concerning its influence in the future, or to predict its permanency, I would suggest, that if I can

show that the whole history of practical surgery has been more or less an empirical struggle to overcome difficulties and dangers, the primary cause of which is now clearly understood, then this fact encourages the belief that the present change, in so far as it is founded on a scientific basis, will be a permanent one. The practical details will most certainly change—are in fact daily changing—and will be improved while the great primary truth on which it is founded will always be our standard. There is a great law governing our physical and mental well-being—namely, that growth and development are accompanied by change, that to stand still and make no advance must necessarily soon be followed by physical and mental decay. Twenty years ago in the treatment of any large recent incised wound, the bleeding arteries were tied with well-waxed silk ligatures. The ligatures were left long and brought out at the corners, or at the most dependent part of the wound. Plenty of cold water was used to wash the wound; the edges were brought together with silver stitches, and a piece of dry lint was laid over the incision and retained in position by a bandage. As a rule this dressing was not touched till the second or third day, when it was removed in consequence of local uneasiness. This removal was always accompanied by a certain amount of pain, which was modified by soaking the lint with warm water before removal. Occasionally, in consequence of the absence of uneasiness, the lint was untouched for a longer period, and removed at the end of a week or ten days to find that union by the first intention had taken place, except at the point or points where the silk ligatures emerged. Sooner or later these ligatures became loose and were removed one by one, when complete healing occurred. The uneasiness complained of was due to local tension as evidenced by redness of the lips of the wound. This redness and uneasiness were relieved by bathing with warm water, or by the application of warm-water dressing (lint and gutta-percha), or by the removal of a stitch or stitches, when the confined discharge escaped as pus. If this pus had a disagreeable odor, then the cavity of the wound was gently washed out with a syringe filled either with simple warm water, or with warm water tinged with Condy's fluid. The wound was dressed night and morning, sometimes even more frequently, and gradual consolidation by means of union by the second intention took place. I make no allusion to the constitutional dangers of which every now and then sad examples occurred, sometimes sporadic, sometimes epidemic, except to say that the principal danger, termed pyæmia, was looked upon as in great part due to the constitution of the patients. The treatment of this danger was entirely curative—quinine, iron, and stimulants were freely administered. Prophylaxis did not occupy the practical mind, because the primary cause of the condition was unknown. Nowadays the treatment of a recent incised wound, as most of you know is very different. The vessels are tied with catgut instead of silk, the ends of the ligatures are cut short, and we see no more of them. The wound is thoroughly washed with an antiseptic lotion, and a drainage-tube, a hank of catgut or of horse-hair, is introduced to the bottom of the wound and brought out at a dependent point. The wound is stitched and a dressing is applied, the essential feature of which is that it contains some antiseptic. This dressing is not interfered with until the discharge soaks through it, or appears at its edges, or unless the wound is painful. This pain is due to an imperfect application of the drainage. The wound is never exposed to the air, but is examined under cover of a cloud of antiseptic vapor.

The wound, as a rule, heals without suppuration and without pain.

Here, then, we have two very different pictures: the main differences between them seem to be, ligatures of catgut instead of silk, free drainage, and antiseptic precautions. Are any of these methods really new? Physic, of New York, Astley Cooper, and others, used catgut; John Vigo and Ambrose Paré recommended drainage-tubes; Würtz alludes to drainage by means of a hank of horse-hair; Guy de Chauliac, Vigo, Arcæus, Würtz, Purmannus, Ambrose Paré, Colbatch, and others used various antiseptics—turpentine, alcohol, camphor, myrrh, and various resins. External dressings were applied containing antiseptics. Watson Cheyne, in his recent valuable work on "Antiseptic Surgery," speaks of Arcæus's treatment as "a fair antiseptic method, and not far removed from an aseptic one." These surgeons whom I have named flourished between 1350 and 1750. During these centuries we find, in the great majority of the surgical works, that much stress is laid upon putrefaction. We find, for example, that Guy de Chauliac, Vigo, and Woodall, define a wound as a solution of continuity—fresh, bloody, and free from putrefaction; and they speak of their remedies as of use in preventing and curing putrefaction. Not only do they mention putrefaction as an evil thing, but we find that Paré, Würtz, Magatus, Colbatch, Belloste, Heister, Benjamin Bell, Alexander Munro, and Abernethy, all considered that the entrance of air into the wound is in some unknown way associated with inflammation and unsatisfactory healing; while Paré and Magatus, in the beginning of the sixteenth century, tell us that the air is charged with miasms, and warn us to avoid such air. In consequence more especially of the teaching of John Hunter and John Bell towards the end of the last and the beginning of this century, these views with regard to the evil effects of the air were almost lost sight of. In consequence, more especially of the teaching of Syme and Liston, simplicity of dressing, such as I have described as made use of in 1860, was the rule in surgical practice. At the same time it is to be noted that the valvular openings recommended by Abernethy, the aspirator long ago recommended by Delacroix and Anel, and subcutaneous surgery generally, retained their place in the practice of surgery. In the beginning of the present century chemists, scientific men, having no knowledge of, and altogether apart from, the practice of surgery, began the study of fermentation, described the products of the process, and searched after the cause. Schwann demonstrated that the oxygen in the air was not the cause, and in 1836 he and Cagniard de Latour discovered independently the yeast plant, and its constant association with alcoholic fermentation. After a time this plant was shown to be the cause of the alcoholic fermentation. Pasteur, in 1858, made the next great step, and pointed out that putrescence is a form of fermentation, and brought forward the doctrine that this is due to organisms planted in a putrescible substance. This doctrine has, up to the present day, been termed the germ theory of putrefaction. This theory is now proved to be correct, and as we speak of Newton's Law of Gravitation, so I am of opinion that we are now in a position to speak of Pasteur's Law of Fermentation. All this work, it will be observed, was done by scientific men, apart from and apparently unconnected with the practice of surgery. For some years before 1860 there were various indications that this scientific work was soon to be utilized in surgical practice, and there can be no doubt that Lemaire the credit is due of having first seen the connection. He used coal-tar and carbolic acid as disinfectants in wounds. It is unnecessary to in-

quire the reason why the work of Lemaire did not gain general acceptance. The fact undoubtedly exists, that his ideas were not adopted by the majority, and that they were even abandoned by those surgeons who had given them a trial.

I would now direct your attention to a paper by Joseph Lister, in *THE LANCET*, in 1867. The paper is entitled, "A New Method of Treating Compound Fractures, Abscesses, etc." Lister, in this his first paper on the subject, gives us the keynote to the position which he then took up, and to which he has ever since strictly adhered. In that paper, after pointing out that the decomposition which occurs in a compound fracture is due to the access of the atmosphere, he says, "We find that a flood of light has been thrown upon this most important subject by the philosophic researches of M. Pasteur, who has demonstrated, by thoroughly convincing evidence, that it is not to its oxygen, or to any of its gaseous constituents, but to minute particles suspended in it, long regarded as merely accidental concomitants of putrescence, but now shown by Pasteur to be its essential cause." He then adds, "All that is requisite is to dress the wound with some material capable of killing these septic germs." Here, then, it will be noted that Lister from the first adopted Pasteur's law as the basis of his practice, and having adopted this law, he then searched out a substance by which he hoped to attain his object. He tells us that in 1864 he was much struck by the advantages obtained by mixing carbolic acid with the sewage of the town of Carlisle. This knowledge encouraged him to try carbolic acid. It is not my intention to dwell upon the gradual development of the practical details. In March, 1865, Lister made his first attempt to form an antiseptic crust, using lint soaked in carbolic acid. This was a failure. After many anxieties and by learning a good deal more from his mistakes than from his successes, always steadfastly holding to the primary doctrine, he experimented first in Glasgow and then in Edinburgh, until in 1871 he elaborated that dressing which is now associated with his name. During all these years Lister was doing a double work; he was trying to perfect the practical details, while he was at the same time working at the germ theory, and doing very much to strengthen the scientific basis of his practice. Many are now working at the practical details. The theory has now become a law. New antiseptics are being daily introduced, and when a more reliable one than carbolic acid for general use has been discovered, no one will more gladly use it than Lister. Much harm has been done by calling his method of treatment the "carbolic acid method," the sole object which he has always had in view being not the use of any special antiseptic or any special plan of treatment, but a method which will enable the surgeon to keep his wound aseptic, from the time it is inflicted until healing has taken place.

It will perhaps be as well here to tell you that in the treatment of wounds their asepticity is only one part of the problem which the practical surgeon has to consider. Lister found that the silk ligature was a source of irritation, and hence arose the reintroduction by him of the catgut ligature. The presence of pus in an aseptic wound directed his attention to suppuration caused by tension—although apart from putrefaction—hence the application of free drainage to all wounds and the avoidance of suppuration from tension. The catgut ligature and free drainage directly were the outcome of a study of aseptic wounds. Do not be led into the too common error that Lister's reputation rests only on his application of Pasteur's law to surgery. His work is threefold in its strength. Do not imagine that a surgeon, in accepting Lis-

ter's teaching regarding antiseptics, thereby necessarily forgets the words of John Hunter: "The first and great requisite to the restoration of an injured part is rest." Many of the most valuable improvements that have benefited mankind have been the result of years of patient and prolonged investigation. These investigations have followed two great lines; the practical man, working by experience and observation, and gradually arriving at some idea of what should be, thinking little of the why; the scientific man, with Bacon as his model, experiment as his mistress, working little by little without any idea of the practical value of his investigations, wading like the practical mind through errors and mistakes, correcting them himself, or having them corrected for him by a future worker, until at last a time is reached when the lines of thought approach one another; then a master-mind, necessarily with both practical and scientific knowledge, able to estimate at their proper worth the value of the sum total of both lines of workers, grasps the double work, and although at first seeing dimly, he steadfastly perseveres until at last he is enabled to establish some great law which will in the future enable the practical mind to work more intelligently, the scientific mind gaining at the same time encouragement to work on, with the knowledge that each little portion of truthful scientific work will in the future bring forth practical fruit. We have a good example of this in the history of the science of astronomy. After Copernicus had shown that the sun is the centre of our universe, Kepler, by a series of calculations demonstrated the elliptical pathway of the planet Mars. A hundred years after, Newton demonstrated the reason why the planet Mars could only move in an ellipse, and showed how all the other planets necessarily followed the same law. It is well known how Adams and Leverrier, using Newton's laws, and working in their studies, told the practical astronomer that if on a certain night he would look in a certain part of the heavens he would see a new planet, which we now call Neptune. While Jenner, by acute observation, discovered vaccination, so we now find Greenfield and Pasteur working on the basis of Pasteur's law of fermentation, and demonstrating by experiment that the bacillus anthracis, which is the cause of splenic fever, can, if modified by cultivation, be inoculated into healthy animals, and give rise in them to a condition which may strictly be likened to the vaccine fever, and which prevents in them the fatal splenic fever, just as the vaccine fever prevents the fatal small-pox.

If such results have been already obtained by careful experiment, is it not legitimate to expect that before long some general law may be discovered by which the poison germs of other scourges, more nearly allied to ourselves, may be modified so as to enable us to limit in no small degree the dire effects of scarlet fever, typhus, cholera, etc.? Pasteur's law, in consequence of Lister's application, has had a revolutionary influence on surgery, there is now good evidence before us that it is doing the same for obstetrics and medicine. Do we not, as citizens, learn from what I have said to-day that it is our duty and our interest to encourage scientific work? I can imagine a visit to Pasteur's laboratory about the year 1860 by a hard-headed successful man of business, who, judging by immediate results—a rapid turn over being the essence of successful trade—would certainly ask himself the question, What possible practical good can ever come to me or to my children from this investigation? As certainly do I feel that, in this utilitarian and practical age, he would leave that laboratory impressed with the

waste of energy displayed, while he would assuredly admire the patience and perseverance of the investigator. I ask this same man to go with me at the present day into an operating theatre, and he will undoubtedly, in all that he sees, be carried back to that former visit, and he will be the first to acknowledge that his former estimate was essentially short-sighted and hasty. If our countrymen could only be persuaded of the great immunity from pain, and the comparative freedom from danger which they can now command, and if it has been demonstrated that these results are directly due to scientific work, based upon experiment, then they would most certainly do everything in their power to aid in fostering the work and encouraging the worker. It must be a law that every truth will in the future bear good fruit. Let each one present remember that "we are all working together for one end, some with knowledge and design, and others without knowing what they do."

What lesson do we learn as workers from what I have said to-day? Let some time be given to the culture of the reasoning faculties, devote a certain portion of each day to self-instruction, self-questioning. Let each of us do a little piece of truthful individual work. Make a start; begin at once; get into the way of doing some special work, and like any habit—good as well as bad—it will grow upon you. If of a practical turn, you will work by experience and observation; if of a scientific turn, you will work by experiment. Both have their value; and even if you only take up the rôle of an overturner of false doctrine, or even a critic of true doctrine, you will all have your use, as Marcus Aurelius says: "Men co-operate after different fashions, and even those co-operate abundantly who find fault with what happens, and those who try to oppose it and to hinder it, for the universe hath need even of such men as these."

One word of warning. The simple treatment of a wound with water dressing was, we now know, imperfect; still the majority were satisfied. Accidents, local and constitutional, were smoothed off and excused by the too common phrase, We had done our best. Let us take care that we do not fall into this error with regard to our present work. As you work, be sure to fight against any temptation which may encourage you to suppose that our knowledge is now perfect. Perfection is not of this world. Is it too much to ask for encouragement for individual work? Some years ago I tried to show that our extra-mural school—a most important factor in our system of medical education—owes very much of its success to the encouragement which is given to the individuality of its teachers, everyone of whom has chosen that subject to which he has devoted special attention. May I now say a word for the individuality of the taught? May I plead toleration and assistance for the man who desires to develop his mental individuality, who desires to concentrate his mind on some special piece of work? There is need for someone to speak out, to "use plain discourse," and to say, that if the public are to require of every candidate for any public duty a universal knowledge, the acquiring of which needs all his energies, then any power which he may originally have had of doing some special work—his individuality, his physical and mental personality—will be crushed out of him. Even our schoolboys are nowadays required to pass a certain standard, the examination system is in full force even in our infant schools. Would we not have more "Lucidity" in the growth of our intellects was less fettered simply directed, rather than pruned and trimmed ordered to do this, forbidden to do that? Any unnecessary interference with the taught at once

tells on the usefulness of the teacher. What opportunity have our schoolmasters to develop any special talent in their pupil when their energies are fully occupied in polishing all their material—good, bad, and indifferent—to one standard? The schoolmaster seems now to have little pleasure in life, he is a mill-horse working round a pivot, a mill-wheel supplied with water to do one thing—namely, polish boys. Let the public see that they take care that those to whom they entrust the education of the medical practitioner are allowed some scope for their imagination, some opportunity to develop the individuality of their students. The essentially evil feature of centralization is its want of personality. Our medical schools still possess some personality; it will be a bad day when that is interfered with. This school to which we happily belong, will lose much of its brightness, will be hampered in its usefulness, if its teachers are compelled to degenerate into polishing machines. May I ever have before me, as an important part of my duty, the encouragement of the individuality of my students. May I be enabled ever to remember that I am dealing with men, each one of whom has some special ability, every one of whom has some special work. May I endeavor, as far as in me lies, to search out that special ability, to encourage and to direct that special work. Give me your help in the future as you have always done in the past; without your confidence I can do little, with it I will endeavor, by devotion to my duties as your teacher, to maintain the reputation of this school for honest work. Working together, let us day by day feel that something has been attempted, something has been done, and at the end of the session we will be able to look back with an inward feeling that, while far from what it should have been, some advance has been made, some problem has been solved. Remember that to everyone present a talent has been given. Let him look to it that he uses that talent aright.

Introductory Address

DELIVERED AT

UNIVERSITY COLLEGE, LONDON,

On the Opening of the Winter Session of 1882.

By MARCUS BECK, M.S., F.R.C.S.

(Concluded from page 415, Dec., 1882).

Thus, then, we have a large number of our students started on their medical education badly, and the consequence is that they spend a great part of their first year of study in learning how to learn, and doing that imperfectly. From want of training in generalization and classification, their knowledge consists merely of a mass of disconnected details, and the strain upon the memory becomes correspondingly great. A thorough and clear comprehension of a subject is essential for its easy acquirement; and without some knowledge of chemistry and physics it is impossible to understand a great part not only of physiology, but of medicine and surgery also. The evil habit of thought which is cultivated by this irregular training in the early part of study frequently persists throughout the whole course, and the difficulty experienced by the student in passing the primary examination is exaggerated in the final, as that includes no subject like anatomy, in which mere memory is of more value than logical thought.

In order to obtain a double qualification, however, the student has to present himself for this

examination at the College of Physicians or the Apothecaries' Hall, and it is very common for this to be done after the College of Surgeons is finished. Consequently we often find him preparing for examination in chemistry and botany some two or three years after he attended the classes on these subjects, and at a time when it is too late for him to derive that mental training from them which should have assisted him in his course of study. Some effort to remedy this evil has of late been made by the College of Physicians by the institution of the new examination to be passed at any time after registration. This, no doubt, is a step in the right direction, in so far as it encourages the student to pass his chemistry and botany at as early a period as possible of his medical study. But, on the other hand, it seems to be specially designed to encourage him to spend some time in a sort of modified apprenticeship before commencing his work at a medical school. Now if the object were to re-establish the old prescribing drug-gist, as he was before the apothecary developed into the general practitioner, nothing could be better; but if the future licentiates of the College of Physicians are to be educated as men of science, the introduction of a period of desultory work without any proper teaching between school and college can do nothing but harm. The botany also, which he is to learn, is defined as medical botany. Now the only justification for retaining botany in the early part of a medical curriculum is, that of all subjects it gives the best training in the accurate observation of simple facts and in classification, and unless it is taught as a science with this object, quite irrespective of its supposed utility in medicine, it might just as well be omitted altogether. Although, therefore, the examination is doubtless a relief to the student, by enabling him to get rid of some troublesome subjects during his first year, it is not likely to do much to improve his training from a scientific point of view, and I believe it is only by an improved training that we shall be able to diminish the lamentable proportion of rejections which forms almost a reproach to our medical teaching. Up to the present time, however, the attempt to meet the higher standard required at the examining boards has been chiefly by increased quantity of teaching, and at the same time the mode of teaching has become more practical and demonstrative. At the time I was a student here there were no demonstration classes in anatomy, the class of practical physiology had not been instituted, and there was no class of practical zoology. Voluntary classes in operative surgery and bandaging existed; but the practical surgery class, as we now have it, was not founded till ten years later. At the hospital the only practical instruction given in surgery was the bedside teaching, supplemented by a few clinical lectures, rather theoretical than practical. In the medical wards students wrote reports on cases which were corrected by the professor of clinical medicine, but no classes had been instituted for practical instruction in the rudiments of medical diagnosis. Now we have changed all this, and practical classes crowd upon each other till it becomes almost impossible to find time for them all in the nine hours of the day during which the college and hospital are open. The practical classes in medicine and surgery have no doubt become necessary to replace the teaching that the student formerly received during his apprenticeship; but in other subjects they have been instituted solely with the view of improving the quality of the teaching, and enabling the student to reach the higher standard of knowledge required of him. The result so far, however, has not been to diminish the number of rejections. These still continue in unabated num-

bers, and will continue, I believe, as long as the present irregular system of education is followed by so large a number of our students. While we expect students to understand the most complicated mechanism in creation without a knowledge of mechanics, to understand the eye and ear without optics or acoustics, or respiration without knowing the laws of atmospheric pressure; while we expect him to understand the chemistry of digestion almost before he knows the difference between an element and a compound, I do not think we can hope for any real improvement in the results of the examinations. It is, I believe, only by a better preparation in science, and by a rearrangement of medical examinations in accordance with the laws of scientific education, so as to train the student to think, and to think well, that we can hope to get any real improvement. To this course, however, many objections have been raised on the grounds that it would add more subjects to the medical curriculum, which, in the opinion of some, already includes more than are necessary; that it would lengthen the period of medical study, and would add another examination to those with which the student is already burdened. Finally, there are some still to be found who deny the utility of science and the value of mental training.

To take these objections in order. First, that it would add another subject to the medical curriculum. I have before said that zoology, although forming an extremely valuable training for those who have time to avail themselves of it, is not essential, and there would be nothing to justify adding it to the ordinary course of medical study. Physics would therefore be the only subject which would be added to those already in the curriculum. Now at the present time, students are expected to know at their examinations all those parts of natural philosophy which apply to physiology, and to the explanation of various morbid processes both in medicine and surgery. We cannot say therefore that it would be added as a new subject. It would be merely taught methodically, and would prove an assistance to the student in his course of study, rather than an increased difficulty. It is sometimes assumed by those who complain of the number of subjects in the medical curriculum, that the student is expected to learn each thoroughly. To learn any subject thoroughly is the work of a lifetime. All that can be expected from a medical student is, that he shall learn the general principles of the various sciences auxiliary to medicine, and shall attain such an amount of knowledge of each that he shall not be altogether lost when he has to apply them to practical medicine or surgery, and that if necessary he shall know what book to refer to for further information, where to look for what he wants, and when he has found it that he shall be able to understand what he reads. The objection therefore to a scientific course of study, that it increases the number of subjects in the curriculum, seems of but little weight.

With regard to the lengthening of the period of medical study, the objection also is more apparent than real. If the period of study were lengthened from four to five years, it need involve no hardship. The preliminary examination in general education may be, and very frequently is, passed at the age of sixteen. The most difficult of all the entrance examinations, the matriculation at the London University, is passed best by well prepared boys between sixteen and seventeen. Now all those who pass at this age must wait five years before they can obtain a license to practice. To these, therefore, it would be no hardship to spend a year in the study of the preliminary sciences. Moreover, if it were understood that a year had thus to be spent,

it would become the custom to send the candidate up for the entrance examination at the earliest possible age. Of course it is much better that the general education should be continued till seventeen or eighteen, but I am only discussing the case of those to whom it is of importance to gain a legal qualification at the earliest possible time, and for them the luxury of a prolonged general education must be dispensed with. It must not be forgotten in discussing this point, that a very considerable number of students are obliged through misfortunes at their examinations, to lengthen their period of study, sometimes to seven or eight years. The number of these unfortunates will probably in the future be greatly increased by the new regulation of the College of Surgeons, which places a compulsory interval of two years between the primary and the final examinations. To many of these, I believe, a period of compulsory training in science would prove a real assistance in shortening their time of study, by enabling them more easily to acquire the necessary knowledge. And supposing the period of study were actually lengthened by a year, we should still be only returning to the old period of apprenticeship which lasted five or even seven years. The student himself should, perhaps, be the last to complain of any prolongation of the time of study, for his time at college will probably be the pleasantest part of his life. An examination now and then no doubt forms a hateful incident during its course, but the real troubles of life begin when the last examination is passed. An examination is no great trouble to a student if he is properly prepared for it, and the addition of a simple preliminary examination in science would, I believe, for the reasons I have already given, tend to make it more easy to prepare for those that follow.

Lastly, we have to consider the objections still occasionally raised to the modern system of education, that the value of mental training is more an idea than a reality; that science is of no direct use to the ordinary practitioner; and that, on the contrary, a scientific education tends to make a man unpractical. To deny the value of mental training seems to me to be evidence of want of it on the part of the person who does so. The argument usually employed is that men are to be met with who go through a thorough course of scientific training, and come out at the end as illogical as they began; and, on the other hand, it is not uncommon to meet with those whose scientific education has been defective, and yet whose mental faculties are developed to a high degree. The fallacy of the argument lies first in the assumption that those whose scientific training has been defective would not have been better had their minds been more correctly cultivated; and, secondly, in drawing the general conclusion that training is of no use, from the exceptional cases in which it has failed to produce the desired effect. I feel myself no doubt whatever that those men learn their medicine and surgery more quickly and more thoroughly who have undergone a proper preliminary preparation in science. Those who manage to distinguish themselves at examinations, and yet remain illogical and unpractical, are, as far as my experience goes, those possessed of a memory of unusual retentiveness, a faculty which is not necessarily associated with a high order of intelligence. There is, I believe, at the present time a hopeless idiot in Earlswood's Asylum who possesses a memory of such extraordinary power that he could, if properly coached, be easily made to take first place in almost any competitive examination.

Of the value of science in the practice of medicine and surgery there can be no doubt. In the first place, to the ordinary practitioner chemistry,

and a certain amount of natural philosophy, are essential if he is to undertake intelligently the practice of hygiene—now as important a department as either medicine or surgery. The post of medical officer of health is one, at the present time, open to every medical practitioner, and often furnishes a welcome addition to the somewhat narrow income of the country doctor. In this post he will be expected to undertake the simpler tests for the adulterations of food and the purity of water, and he will be required to give advice on questions of ventilation, heating, and warming, and on numberless other subjects in which some knowledge of science is involved. But the innumerable applications of science to modern medicine and surgery are of no less importance. With regard to medicine I would not venture to speak, but I have no hesitation in saying that the wonderful advance which has been made in surgery during the last twenty years has been entirely due to the application to it of science and the scientific methods of investigation. During that period surgery has made more real progress than at any previous time in its history; and this progress has been chiefly due to the discovery of the nature and causes of surgical fever, and of spreading and infective inflammations. It commenced as late as 1866, by the application of Pasteur's discoveries to practical surgery by Mr. Lister. For centuries before this time the necessities of cleanliness in wounds had been well known, and antiseptics had been employed by all surgeons in their treatment down to the early part of this century; but so little were their properties understood, and so doubtful had been the advantages derived from their use, that at the time I was first a dresser in another hospital, twenty years ago, they had been almost completely abandoned, and wounds were treated either by the application of a dry dressing, which was removed when the smell became intolerable, or by placing over them a piece of lint soaked in simple water and frequently changed. Water alone, without the addition of any antiseptic, was used to wash away the discharges. It was only when the discoveries of Pasteur showed us that so-called clean water is in fact one of the dirtiest things in nature, that this treatment was abandoned. Yet while this treatment was being adopted, and it was possible to tell by the smell alone whether you were in a medical or surgical ward, surgeons were constantly insisting upon cleanliness as the most essential feature in the treatment of wounds, so little idea then existed of what true cleanliness is. Dirt at that time, in the form of putrefying discharges, was considered inevitable; cleanliness consisted in clearing away the decomposing matter: the higher scientific idea of cleanliness, as consisting in the absolute prevention of decomposition, was impossible till Pasteur's discovery had shown to what decomposition is due.

About the same time that Mr. Lister was introducing the antiseptic system of treating wounds, Bergmann and others were, by carefully devised experiments, proving the fact that the high fever which then almost invariably accompanied all large wounds and severe injuries was due to the absorption by the surface of the wound of the chemical products of putrefaction contained in the decomposing discharges. The investigations into inflammation and the allied processes were at the same time establishing as a pathological fact the absolute necessity of an abundant decomposable exudation from the raw surface of a wound during the first few hours after its infliction. To provide a sufficient exit for this discharge by a proper system of drainage became, therefore, an essential feature in the scientific treatment of wounds.

Drainage, like the use of antiseptics, was nothing new. Tubes made of metal, and tents of various kinds, were used centuries ago, but, as with the antiseptics, their use was not founded upon scientific principles; and in the anxiety to avoid the introduction of foreign bodies they were completely abandoned, so that twenty years ago such a thing as a drainage-tube in a fresh wound was hardly thought of. Empirical surgery had tried both antiseptics and drainage, and had abandoned them as useless. Scientific surgery showed their real value, and although the present methods will undoubtedly undergo modification, these two great principles must remain as essential features of every mode of treating wounds. It is to the scientific mode of treating wounds that we owe all the marvellous progress of surgery during the last sixteen years. This progress is not to be judged of by the number of new operations that have been introduced into practical surgery, nor by the heroic nature of some of those recently performed, but rather by the improved results of the common operations, and the greater success that attends the treatment of common injuries.

The study of the unhealthy processes in wounds is still advancing in the hands of Koch and others, but there still remains much to be done. Unfortunately in this country the means of carrying on such investigations are surrounded by so many legal difficulties that we are obliged to trust chiefly to foreigners for new matter, but we can take our share in applying the discoveries of foreign pathologists to the practical treatment of diseases, and to prepare us for this a proper scientific training is a necessity.

That a scientific education tends to make the student unpractical is another argument sometimes used. It is but a poor compliment to our profession to assert that those practice it best who know least about the nature of the diseases they undertake to cure. The complaint as to the want of practical knowledge in the students educated on the modern system comes chiefly from the general practitioner, who asserts that the present student fresh from his college and hospital is of but little use to him as an assistant. If called upon to dispense he is ignorant of how to make his mixtures pleasing to the eye and palate, his pills are too big, his plasters too thick, and the parcels he makes up are badly folded and inelegant, and his knowledge of book-keeping is even more limited than his acquaintance with pharmacy. When a patient has nothing the matter with him he tells him so in so blunt a manner that he immediately seeks out another medical man, who will be a little more sympathetic with regard to his supposed sufferings. He looks upon every patient too much as a case, and fails in all those legitimate arts which are necessary to win the confidence of that most selfish and unreasoning of beings. A still more serious failing often shown by the modern student is, an ignorance of the various infectious diseases which are not admitted into general hospitals. There is no doubt, therefore, that the general practitioner has just cause to complain when asked to give a hundred a year to a man who, however well trained in medical and scientific knowledge, is totally ignorant of the business element which necessarily forms a part of our profession. He finds that he has to pay a man for learning from him that which in the days of apprenticeship he was handsomely paid for teaching. The only remedy for this seems to me to be in the hands of the general practitioner himself. He should refuse to give more than board and lodging to any man who has not had six months' experience of actual practice. Six months of such experience would be quite sufficient, and at the end of that time, I have

little doubt, the modern student would practice his profession none the worse for possessing a better knowledge of the principles which guide his treatment.

One advantage of a proper scientific training, to which I have not yet alluded, is that it tends to fit every medical man to take his part in advancing medical knowledge, should he feel the inspiration to do so. The general practitioner is placed in circumstances which enable him to observe certain points in clinical medicine and surgery much better than the consulting physician or surgeon. He sees most of his cases from beginning to end; he can observe those preliminary symptoms which indicate the approach of grave disease; and he has the opportunity of verifying his own conclusions and those of such consulting physicians or surgeons as the patient may have seen. He has unusual opportunities of studying the influence of heredity, of occupation, and of locality on disease, so that, should he feel inclined, he has no lack of opportunity of prosecuting original investigations. A proper scientific training will teach him the method of conducting such investigations, the precautions necessary to avoid error and the utter worthlessness of opinions formed merely as the result of experience, and unsupported by accurately recorded observations. Such original research would be of all the more value, as it would, in most cases, be spontaneous, and undertaken purely from the love of the work, and not, as is so much that is done in the present day, merely with the view to say or do something new in order to obtain promotion either in a hospital or medical school.

Supposing it then to be granted that the best training for every student should include a preliminary education in science, how could such a scheme be carried out? In the first place, it is absolutely necessary that the examinations should correspond to the course of study. Taking sixteen as the age at which a boy could pass his preliminary examination in general education, he could then immediately turn his attention to science. There is no reason why this should not be done before leaving school. At Epsom Royal Medical College students are now prepared for the preliminary scientific examination of the University of London, and there ought to be no difficulty in preparing for a similar examination of a lower standard at any good school. If there were a demand for such education the supply would soon be abundant, and after passing the entrance examination the boy could, if necessary, be moved to some school where the required instruction was given; or, if his parents preferred it, he might at once enter at a college, and enjoy the advantages such institutions naturally possess. The examination in science might take place at seventeen. The subjects of the examination would be chemistry and natural philosophy, and either botany or zoology, or both. After passing this the student could commence regular medical study with a much better chance of making good progress from the very beginning. At the end of the second year, and at the age of nineteen, would follow the examination in anatomy, physiology, and materia medica, and perhaps in applied chemistry, and the remaining subjects at the end of the fourth year of study, when the student had reached the age of twenty-one. Part of his last year of study might doubtless with advantage be spent in receiving instruction from a general practitioner.

There seems nothing impracticable in such a scheme as this, but in order to carry it out it is absolutely necessary that the present disjointed system of examination so often followed, in which some subjects are passed before one examining

board, and others before another, should be in some way made impossible. The conjoint scheme does not seem, however, to be as yet within the range of practical politics. The report of the Royal Commission which has just been sitting seems, in the absence of compulsion, to leave us much where we were before. In fact, the idea of a harmonious conjunction between bodies so different in tradition and in character as the University of Oxford and the Society of Apothecaries is, perhaps, somewhat Utopian. It is not, however, necessary for the whole seven licensing bodies of England to conjoin to produce the desired result, so far as the student is concerned. The universities have already expressed a willingness, and are, in fact, empowered to cease giving their graduates a legal right to practice. That they should thus be ready to give up one of their most ancient privileges makes it more to be regretted that they were not equally willing to renounce any direct part in the appointment of examiners, and in the management of the proposed conjoint examination. If the universities retired we should have left, as far as England is concerned, only the three corporations; and it at first seems rather surprising that these three bodies find it so difficult to sink their differences, and unite for the purposes of examination. This surprise will, however, be somewhat lessened if we look back at their history; and it may not be uninteresting to you if, in conclusion, I try, as shortly as possible, to trace how these three bodies have arisen, where we only want one, as I think a review of their history may tend to suggest a remedy for the evil.

In the early part of the reign of Henry VIII. the medical profession consisted of physicians who had received licenses to practice both medicine and surgery, either from the bishop of the diocese or from the Universities of Oxford and Cambridge, but who were not united into any corporate body, and of "two several and distinct companies of surgeons, one called the Barbers of London and the other the Surgeons of London," the former having been incorporated as far back as the year 1461. Outside the profession were the apothecaries who kept drug shops. These were under the control of the Grocers' Company, and had no legal right to practice medicine. In 1518 Henry VIII. granted letters patent, constituting the College of Physicians. From its very foundation it was a body of great dignity and power. The Physicians held a social position much higher than the surgeons. Most of them had received an academic education, and were possessed of some degree of culture. The surgeons were as often as not rude uncultured men, their professional education consisted entirely of an apprenticeship to some freeman of the company of barbers or surgeons. About twelve years after the foundation of the College of Physicians, the two companies of the barbers and surgeons were joined into one; yet curiously enough, any single member of the company was forbidden to practice both the mysteries of barbering and surgery at the same time, unless he was the domestic servant of some great man. This was to prevent their spreading disease, by opening foul abscesses and shaving with the same instruments. The surgeons were kept closely confined to the mechanical part of their art, and if they ventured to order a dose of medicine, they were fined and imprisoned without mercy by the President of the College of Physicians.

For a short time they had, however, the satisfaction of tormenting the apothecaries in their turn, if they ventured to undertake the care of surgical cases. But this happy time for the surgeons was of short duration, for three years after the two companies were joined, an Act was passed, in the

preamble of which they were accused of "vexing divers honest persons, as well men as women, whom God had endued with the knowledge of the nature of herbs, roots and waters;" of "extorting money from the diseased," and of "having so small cunning, that by reason thereof, they did sometimes impair and hurt their patients rather than do them good." Wherefore, it was enacted, that practically anyone might practice surgery who thought he had a gift in that direction.

For a long time after this, the physicians had the pleasure of tyrannizing over both the surgeons and the apothecaries. The apothecaries had the advantage of the assistance of the powerful Company of Grocers, of which they formed a part, until the reign of James I. Then for the first time they were incorporated, but it was not till a few years later, in 1616, that they were definitely separated from the grocers and established as an independent company, under the name of the Society of Apothecaries of London. They were not, however, free from the College of Physicians. Either the President, or some physician delegated by him took part in the examination which had to be passed before an apprentice could be made free of the company, and the duty of inspecting and destroying adulterated drugs, which was transferred to them from the grocers, was carried out in conjunction with, and at the command of, the physicians. The apothecaries were the pharmaceutical chemists of that time, and, like the chemists of the present day, seem to have taken every opportunity of prescribing as well as of dispensing medicines. At first the College of Physicians resented this, and summoned many apothecaries before them, and fined some and "excommunicated," or, as we should say in the present day, "boycotted" others. Still the practice grew, and at last the apothecaries claimed the right of prescribing as well as dispensing. The struggle between them and the physicians was long and bitter, and it was not finally settled till a judgment was given in their favor in the House of Lords in 1708. During this time the surgeons and barbers remained united, and it was not till 1745 that they finally parted company, the surgeons establishing themselves independently in Surgeons' Hall, as the Corporation of Surgeons of London.

In 1748 the apothecaries obtained an Act of Parliament which confirmed their power of prescribing medicines, gave them additional powers of examining, and made it illegal for any man to dispense medicine within seven miles of London without their license. It now became common for medical men to hold both the licenses of the apothecaries and surgeons, and thus arose the so-called surgeon-apothecary, and in his hands was the greater part of the practice of the country. After they were beaten by the apothecaries the power of the physicians rapidly declined, and they seem to have retired into a state of sulky and offended dignity, and not to have taken the part they might have done in controlling the education of the lower grades of the profession. At the end of the last century the Surgeons' Corporation seems to have died a natural death, and now was lost the great opportunity of uniting the physicians and surgeons, which will probably never return. The College of Physicians has always maintained that surgery is only a branch of medicine, and that their license entitles its holder to practice both; and it is much to be regretted that they did not act upon this assumption. At the time when surgery was practiced chiefly by illiterate men, who also undertook the trade of "barbery," any union between the ignorant barber-surgeon and the cultivated physician was out of the question. But in 1800 things had changed, and the physicians need

not have felt it beneath their dignity to welcome within their body a class of men amongst whom had but recently been Percival Pott, Cheselden, Sharp, and John Hunter. Yet although many surgeons also recognized the inseparability of medicine and surgery, the idea of uniting the physicians and surgeons seems never to have been entertained, and the College of Surgeons in its present form was founded. Possibly if this desirable union had taken place, the encroachments of the Society of Apothecaries might have been withstood. As it was the surgeons became rather the allies of the apothecaries, and upon the surgeon-apothecaries fell the task of raising the lower grades of the profession to a higher and more dignified position. Under their influence was passed the Act of 1815, which gave the apothecaries further powers of examining, and extended their jurisdiction to the whole of England and Wales. This Act was evidently intended to perpetuate a lower grade of the profession, who should combine the trade of the druggist with the practice of medicine. That this was so is shown by the fact that the apothecary was bound under heavy penalties to prepare prescriptions ordered by a physician. It was also intended that the chemist and druggist, who was now arising as an independent tradesman, should not be allowed to prescribe. The apothecaries were not, however, content with this inferior position, their ambition being to grant a license on equal terms with the College of Physicians. They consequently limited their apprenticeship to five years, and made attendance at a medical school compulsory; and it cannot be denied that at this time they did more to raise the general standard of knowledge in the medical profession than any other body. While doing this, however, they neglected their proper business, and allowed their influence in the drug trade to slip from their hands till, in 1841, a separate society—the Pharmaceutical Society of Great Britain—was established, which relieved them from their last duties in connection with that trade. Finally, the Act of 1858 practically made the licenses of the two Colleges and the Apothecaries' Society equal. At the same time some of the evils that it was intended in 1815 to correct have reappeared in an aggravated form. By the destruction of the old apothecaries, who sold their drugs and gave their advice for nothing, the field has been left open to the chemist and druggists, who now probably do about as much practice as the legitimately qualified medical men. The apothecaries are thus as it were "hoist with their own petard." They have raised the general practitioner till the College of Physicians has at last condescended to take notice of him, and arrange a suitable examination for his benefit. They have lost every trace of influence in the drug trade, and their license confers no special privilege on its holder; and it need not be said that few would not prefer the letters L.R.C.P. after their names to L.S.A. Consequently, all reason for their continued existence has disappeared. It is useless to plead as an extenuating circumstance, that they did good work in raising the general practitioner sixty years ago. They have forgotten that it is said "Be not weary in well-doing," for they seem soon to have wearied, and practically for the last quarter of a century they have done less to improve medical education than any other body in this division of the kingdom, the University of Oxford perhaps excepted. But it is not likely that they will retire from the false position into which they have thrust themselves; it could hardly be expected from human nature. To call in the aid of the State would be a great calamity for the medical profession, which has so far managed its own affairs. There is, however, another alternative and that is,

the union of the two colleges for the purpose of examination. The College of Surgeons now holds a position of nearly equal, if not equal dignity, with the College of Physicians. To this it has arrived by the improvement of the science and art of surgery, which it represents. It has, perhaps, done its duty better than either of the other corporations. It has never allowed the control over surgical education, from the highest to the lowest grade, to slip from its grasp, nor has it until quite recently undertaken any duties properly belonging to another body. The union for the purpose of examination of such a body with the physicians ought to present no difficulties, and if it were effected the Apothecaries' Society would probably before long die a natural death. No further conjoint scheme would be wanted for England. At present something is urgently required; not so much to protect the public from ignorant practitioners, for that I believe is sufficiently done by all the examining boards, but for the protection of the student from the present irregular, unscientific course of education which he is so often allowed to follow.

Introductory Address

DELIVERED AT

ST. THOMAS'S HOSPITAL,

On the Opening of the Winter Session, October 2nd, 1882.

By SEYMOUR J. SHARKEY, M.A., M.B. Oxon.,

Assistant-Physician, Joint Lecturer on Pathology, and Demonstrator of Morbid Anatomy at the Hospital.

(Concluded from page 418, Dec., 1882.)

Of course it remains a question of degree whether improvements in the treatment of diseases have kept pace with the increase in our knowledge of them. But that great improvements have been made admits of no doubt. One of the most important outcomes, however, of our advances in physiology and pathology and the natural history of disease is that we have recognized the following facts: that many affections are incurable, that they depend upon certain definite causes, and that these causes are often avoidable. Hence the importance of what is now termed "preventive medicine." In our treatment of chronic diseases we place our patients, as far as we can, in conditions which arrest the progress of the morbid changes which are going on in their organs. But why not prevent these changes altogether? This must evidently be our aim both now and in the future; though it is very questionable whether people will ever have the wisdom to submit to restrictions and rules of life in order to avoid miseries which they have never tasted.

There remains yet another department of therapeutics, to which the profession may point with feelings of legitimate satisfaction, and that is the application of surgical methods to cases upon which the administration of drugs or any other treatment whatsoever can necessarily have but little effect. The diseases referred to are abscesses in some of the large parenchymatous organs, collection of pus in serous cavities, the various forms of acute and chronic intestinal obstructions, the partial or complete removal of diseased organs, etc. The possibility of treating such affections depends of course upon our ability to diagnose, or at least suspect, their presence. And it is the increasing power which the progress of our science in various directions has given us of

localizing disease which has made these surgical procedures in any degree feasible. But the most important factor of all in these modern improvements has been the introduction of antiseptic surgery. Whatever may be the true *rationale* of Lister's method, whether the details he recommends need to be carried out in their entirety or not, or whatever may be the opinion of individuals regarding it, every unbiased man must confess that it has produced a revolution in that department of surgery which was formerly the field of the most unsatisfactory and fatal operations. The comparative impunity with which antiseptic surgery allows us to manipulate the peritoneum and other delicate and sensitive structures has not only resulted in the successful treatment of many patients, who would formerly have perished under the same ordeals, but it has likewise emboldened the surgeon to attempt operations which he would not have dared to do before, and even to make explorations in cases where life is threatened by obscure conditions.

To sum up, then, what can be said for the principles of modern treatment? We have thrown down the idol of universal specifics, which men had hewn out of false conceptions of disease. We have set up in its place rational scientific treatment, founded upon the knowledge of physiological processes in health and in disease; and we aim, as far as drugs are concerned, at the discovery by observation and experiment of the physiological action of substances which can then be used with greater precision in therapeutics. And although this rational pharmacology is still in its infancy, we already possess some drugs the action of which we fairly well understand. We have a few remedies which appear to have just claims to the title of specifics, and we still harbor a probably legitimate hope of discovering others, which may be effectual in certain diseases before they have produced serious organic lesions. Great strides have been made in medical surgery, and we seem likely to advance still further in this direction. But our grandest aspirations lie in the path of preventive medicine, a department which should not only embrace attempts to exterminate some diseases, and to diminish the number of persons who fall victims to others; but must likewise include efforts to prevent the extension of morbid processes which have already begun in the organs of our patients, by regulating their lives in accordance with the teachings of physiology.

It will now be evident to you, gentlemen, that if the general view I have put before you of the principles of modern medicine be correct, there is an interdependence between all the subjects which are embraced in the medical curriculum, such as did not exist in former times. Clinical medicine has to be studied in the light of pathology, pathology in the light of normal anatomy and physiology, and the latter in the light of chemistry and physics. Nor must it be forgotten that what has really given medicine a claim to be placed among the sciences is the recognition of physiology as its basis, and what has given physiology itself precision is the experimental method of investigation. We do not for a moment assert that without vivisection there would be no physiology; but the irreconcilable opponents of the former cannot even be convinced of the great advantages which have resulted to physiology and to medicine alike from the practice of experimenting upon living animals. The fault, however, lies with the anti-vivisectionists, and not with us. For the foundation of medicine is physiology, and one of the essential factors in accurate scientific physiology is experiment. To appreciate these propositions one must first realize the facts and history

of physiology and of medicine. But this cannot be done, though some insist that it can, by people who have little or no knowledge of these sciences. The answer to those who would suppress vivisection altogether lies not in quoting individual useful applications to medicine of facts which have been discovered entirely by vivisection, but in pointing to the comparative precision which pervades the whole of modern physiology, and which is gradually being introduced into practical medicine, a precision which we owe to experimental methods of research.

True scientific principles are as old as Hippocrates, but the field of observation has been widely extended. With all our increase in scientific knowledge, however, it is no easier, probably harder than ever, to become a good practitioner. A man might know everything and yet be a very bad doctor. Now, as of old, no amount of book-learning will make up for deficient dexterity in the examination of patients, or for the want of clinical experience. All methods of investigation must be carefully learnt and skilfully applied. Stores of knowledge must be at command, and the reasoning powers must be called into play to a degree probably not surpassed in any other profession. The best means of ascertaining what is really the scientific method of medical practice is to watch the work of a good physician by the bedside. A few years ago this school had to mourn the loss of one of its brightest luminaries, Charles Murchison, an eminent scientific physician and consummate teacher. His wide and varied knowledge of anatomy, physiology, and pathology, which he applied with such ability by the bedside, his splendid powers of observation, his keen logical acumen, his clear and easy exposition, and his contagious enthusiasm, formed a whole the charm of which has rarely been equalled, and can never be forgotten by his pupils. Nor can we mention Dr. Murchison without being reminded of another loss which we have this year sustained in Dr. Peacock, long a member of our staff, whose methodical and accurate observations have placed him among the highest authorities in more than one obscure region of pathology, and whose lively interest in medicine was shown by the eagerness with which he clung to the duties of his profession up to the last moments of his life.

But it may be asked, Have the modern methods been productive of good unalloyed? Are there no evil tendencies to be striven against? The increasing power of localizing disease, with which we have just reason to be satisfied, frequently leads practitioners to look upon the body as a number of separate organs, each of which has its own peculiar affections and its own proper methods of treatment. The grand object often seems to be to diagnose the disease, and then to prescribe drugs said to be beneficial in it. But if physiology has taught us one thing more certainly than another, it is the intimate union of the individual parts of the body to form a concrete whole. One organ cannot be deranged without altering the conditions which surround the others, and interfering with the healthy composition of the blood and with the normal course of nutrition. Moreover, some organs are united by even closer bonds, in the form of nerve communications; or they have some similarity of function, which enables them to a certain extent to act vicariously for each other. Consider the innumerable derangements of health referable to almost every part of the body, which may result from the physiological cessation of the functions of the uterus and ovaries at the climacteric. In this instance energetic factors in the production of the vital equilibrium suddenly cease to exert their influence. The patient has lived

long enough to have alterations of an abnormal kind produced in some of her tissues. These, if they are not fanned into a blaze by changes which then take place in their nutrition, are at least productive of functional disturbances within the area which they occupy. This is a typical instance of a condition which affects not one organ only, but the whole vital equilibrium, and the re-formation of the latter on an altered basis sometimes takes years to effect, sometimes is the source of never-ending ill-health. In any case a rational and effectual treatment must rest, not on a consideration of the state of one organ alone, but of all the physiological processes which take place within the body. Nor is this an isolated example. A very large proportion of local diseases produce widespread effects on the organism in general, and cannot be rationally treated by confining our attention to the part which is most conspicuously at fault.

Another offspring of modern medical thought is the tendency to scepticism—a tendency which we must not sweepingly condemn. It has arisen mainly with regard to the treatment of disease by drugs, and is the natural result of increasing knowledge. When a medical man studies disease from our present point of view, and is brought face to face with the wreck which it makes of the most vital structures, he must indeed be illogical if he does not rapidly cease to believe in the efficacy of any drugs whatsoever, either to repair the damage done, or to act as a substitute for the diseased organ in the economy. This scepticism regarding the possibility of finding specific cures for diseases in general is a most laudable trait, and shows an appreciation of the principles of modern therapeutics which is likely to lead to a far more effectual treatment of the patient than any blindly empirical administration of remedies.

But, gentlemen, you must not misunderstand me, and suppose that I have less confidence than I really have in our Pharmacopœia. I believe it to be composed of—first, a small number of very useful drugs, the physiological action of which is known, and the application of which to diseased conditions is of incalculable value; secondly, it contains a considerable number of remedies, the efficacy of which has been proved in many abnormal conditions, though the *rationale* of their action is still unknown; and, lastly, it contains a host of articles which some people assert to be useful for one thing, some for another, but about which very little of any value is known. Now the sceptic, who seems to me to be culpable and unscientific, is not he who has no belief in, and consequently discards, the motley collection of substances contained in the third category, but he who declines to use any drugs except those of the first, the physiological action of which is well understood, and for the administration of which he can see a *rationale*. Such a one will not use those medicines, the properties of which have been ascertained by a long series of observations, while their mode of action is obscure. This is an illegitimate and reprehensible scepticism. For although it must be the aim and glory of medical science to add constantly to those drugs the physiological action of which is known and the application of which to disease is so much the more certain; still the medical art must always remain one of observation and experience, and it is rational and scientific to act upon the results of these, though we may have long to wait for an explanation of what occurs.

It has often been remarked that the best physicians use few drugs, and, compared with the whole contents of the Pharmacopœia, the rational scientific sceptic will have only a small number of remedies which he cares to prescribe; but making

himself by constant observation more familiar with their action, and with the conditions to which they are applicable, he will use them rather as arms of precision, and his treatment will be to the point and effectual; while what may be called the "mitrail-lense" system of the less sceptical practitioners of former days relied rather upon the number of substances which were mixed together in the hope that some might hit the mark.

In the short account which I have presented to you of what appear to me to be some of the leading principles of thought in the medicine of to-day, I have implied that we are entitled to feel a certain degree of satisfaction in the progress which has been made. But let us remember that what we now know, and what we can accomplish by our art, is but a very small fraction of that which will one day be achieved by our successors. Let us make a modest estimate of the present state of science, and not give anyone in future times the opportunity of quoting boastful utterances of ours, as I am now about to quote a surgeon who flourished some three centuries ago. Ambrose Paré wrote thus—"God is my witness and all good men know that I have now labored fifty years with all care and pains in the illustration and amplification of my art, and that I have so certainly touched the mark whereat I aimed, that antiquity may seem to have nothing wherein it may exceed us beside the glory of invention, nor posterity anything left but a certain small hope to add some things, as it is easy to add to former inventions." Let that be a warning to anyone of us who is inclined to exult in the present state of science, which may have made more progress at the end of the next three centuries than it has since the time of Ambrose Paré.

In days gone by many a sect, many a system of medicine has flourished and decayed, and whatever truth existed among their errors has been built into the scientific fabric of to-day. Homœopathy alone remains. But even homœopathy has discarded many of the absurdities of its founder, Hahnemann. It professes to accept and be guided by the data of modern science, and to differ from us only in the treatment of disease. It seems to me, too, that many professed homœopaths have practically retired even from this position, and have faith no longer in "dynamization" and infinitesimal doses, but hold merely to the theory "*Similia similibus curantur*." This dictum is a distortion of a truth, and should express nothing more than this—that if we give drugs in large poisonous doses, we ascertain by the symptoms produced the organs on which they act, and we then administer them in smaller quantities when we wish to elicit their physiological action in cases of disease. The truth which is really involved in "*similia similibus curantur*" is nothing more than the elective affinity of certain drugs for certain organs, and the fact that if given in poisonous doses they derange the action of these organs. But this is not a method of experimental pharmacology which is characteristic of homœopathy, but one which has long been used in ordinary common sense medicine. Those homœopaths who differ from us in little more than this theoretical question, as to why certain drugs are indicated in certain diseases, have no right to place themselves under the banner of another sect, thereby deceiving the public, who are led to believe that their imposing name implies a *bonâ-fide* difference in practice. But the rest of the homœopaths, if there really be a remnant, who can plead that they honestly believe in infinitesimal doses, in the dynamization of drugs by trituration and dilution, and in other palpable absurdities, may practice upon a deluded section of the public, but cannot possibly be received as the colleagues of

reasonable men. No, gentlemen, the day has long gone by when systems of medicine were admissible. There is but one system—the scientific,—which rests upon observation and experiment, and upon the application of science in general as a guide to the knowledge and treatment of disease. Therefore avoid being led astray by the seductive theories of any sect whatever. Be neither homœopaths, nor allopaths, nor antipaths, nor any other "paths," but scientific medical men. And if you really are such, you will secure one of the greatest sources of happiness through life, one of the greatest consolations in its many uncertainties—an enthusiasm for your profession. And having that, you cannot fail to feel also a love and enthusiasm for the school where you first became imbued with the principles of scientific medicine.

ABSTRACT OF A

Clinical Lecture

ON

HÆMORRHAGE INTO THE CAVITY OF THE ARACHNOID:

ITS SURGICAL AND MEDICO-LEGAL ASPECTS.

Delivered at the Middlesex Hospital, on Jan. 17th. 1882.

By HENRY MORRIS, M.A., F.R.C.S.,

Surgeon to, and Lecturer on Surgery at, the Hospital.

THE subject of hæmorrhage into the inter-arachnoid space has been one of the battle-fields of pathologists. The source of the blood is generally difficult to trace. It has been thought at one time to proceed from one of the vessels of the dura mater, at another from the pia mater; or, again, from one of the small veins which cross between the brain and the large venous sinuses of the dura mater. Probably it rarely comes from a vessel of the dura mater, because blood from such a source, whether the skull be fractured or not, is far more likely to separate the dura mater from the bone and escape into the space between. When the brain is lacerated and the visceral arachnoid torn, the blood found in the inter-arachnoid space is pretty sure to have come from the pia mater. Such cases are comparatively common. But if there be no fracture of the skull, no injury to the dura mater, no tear in the visceral arachnoid, and no bruising or laceration of the brain, it is impossible to say whence the effused blood is derived.

Then as to the state of the effused blood. It may be liquid or solid. If solid, it may be coagulated in clots, or in a thin membranous layer covering more or less of the convexity of the cerebrum. If in the form of a membrane, it may become a bond of union between the visceral and parietal arachnoid; or it may be adherent to the arachnoid covering the dura mater, but free on its under surface; or it may be quite non-adherent on both its aspects. In either the fluid or the solid state, if it retain all or nearly all the natural color of the blood, and if it have none of the characters of false membrane or of a cyst, there is no room to doubt as to its nature. But when in the inter-arachnoid space there have been found layers looking like false membrane with more or less altered blood in them; or when these layers have consisted of yellowish fibrine only, with or without effusions of recent blood, in the form of small cysts, between them; or, again, when, as in some extravasations of old date, the mass has assumed the appearance of a single complete cyst containing blood, and has

perhaps fallen out entire from its position—much questioning has arisen. In all such cases, the question has been whether the cyst-like membrane has been formed from the extravasated blood itself; whether the blood causes the false membrane by inflammation, and thus an exudation of lymph surrounds the extravasation; or whether a vascular false membrane yields the blood by bleeding.¹

The blood may become so firmly attached to the arachnoid surface of the dura mater as to appear like a thickening of that membrane. Or it may be so closely fixed to it by a smooth and glistening serous-like covering as to look as if the blood were effused between the dura mater and the parietal arachnoid; but such can be proved not to be the case by peeling off this false membrane, and thus exposing the parietal arachnoid, roughened and discolored it may be, but still adherent to the dura mater.

Ample evidence has been produced by the French pathologists, and by Sir George Burrows, Mr. Prescott Hewitt, and Dr. Wilks in this country, that all these various appearances result from extravasation of blood between the layers of the arachnoid.

But besides their great interest to the pathologist, these interarachnoid effusions are of much importance to the practical surgeon. They have been met with after blows and falls upon the head, sometimes associated with fracture of the skull, sometimes with brain bruising, sometimes with both, at other times with neither. They give rise to no symptoms which are pathognomonic, or which even suggest, with any definiteness, their presence. The symptoms, as coma and paralysis, which they excite, may be delayed for an indefinite period, and are liable to intermissions dependent upon recurrence of hæmorrhage, or in old cases upon the more or less rapid absorption and effusion of the cyst fluid. Even when immediate symptoms of compression occur, neither the nature of the accident nor the character of the injury to the head affords any clue whatever to the exact locality of the blood. Nor does the apparent slowness of the hurt, or the entire absence of symptoms, exclude the probability of meningeal apoplexy; neither is there any evidence to show that the evil consequences of these extravasations are hastened or delayed by the observance or otherwise of absolute rest, regulated diet, and medicinal treatment, after the accident which has caused the hæmorrhage. This is much to be regretted; for although in many cases surgical interference would be useless, yet in others could we with certainty tell the exact situation of the effused blood, the well-timed employment of the trephine might make all the difference between restoring the patient to health on the one hand, and of early death from compression, or prolonged years of constant headache, impaired senses, altered disposition, epilepsy, and even insanity, on the other.

To the surgeon, moreover, these inter-arachnoid effusions have a very important medico-legal bearing, for he may be called upon to express an opinion as to whether the hæmorrhage is the result of violence or not; and the life of an accused person may largely depend upon the surgical evidence. Now, as it is with regard to the source of the hæmorrhage and the condition of the extravasated blood, so it is with regard to the cause of the hæmorrhage. There are cases in which there is scarcely room for doubt, but there are others in which opposite opinions might plausibly be advanced. Extravasations of blood in the arachnoid occur from injury, but, as Mr. Prescott Hewitt has

said, they "are generally met with in cases where there has been a decided determination of blood to the head by whatsoever cause produced. I have met with them in cases where there has been great anxiety of mind, in poisoning of opium, in drunkards, in delirium accompanying phthisis, in maniacal patients, and in aged people, in whom I think these effusions depend oftentimes upon the atheromatous deposit in the arteries of the brain and its membranes."²

In the Guy's Hospital Reports for 1859³ Dr. Wilks has reported in abstract eight cases of sanguineous meningeal effusion (apoplexy), in some of which the extravasation into the arachnoid cavity was certainly spontaneous, the result of Bright's disease or anæmia, in others as certainly due to a blow; whilst in others the cause was dubious, because, though violence had preceded death, there was such a diseased condition as might of itself have given rise to the hæmorrhage.

In dubious cases two questions may be raised in defence of a person accused of murdering the subject of an inter-arachnoid hæmorrhage. 1st. Was not the hæmorrhage the result of a diseased state of the blood or tissues of the deceased, or of over-excitement? 2nd. If disease or excitement was not the immediate cause of the hæmorrhage, was it not a strong predisposing cause, and would the same amount of violence have excited fatal hæmorrhage in a perfectly healthy person?

No question of the sort arose in the case I now am going to relate, because the scalp wound was caused by a fall, but had it resulted from a blow or from something thrown at the deceased, with intent to injure him, one or both of these questions would have been put to the surgeon. And like so many other questions, it would have been much easier to put than to safely answer them.

CASE 1. *Scalp Wound, Delirium Tremens, Extravasation of Blood into the Arachnoid Cavity; Death.*—James J—, aged thirty-one, was admitted into Brodrip Ward on the 14th of December, 1881. He had been spending a fortnight in dissipation at Brighton, during which he was more or less drunk (generally more) every day. On the morning of December 14th he arrived in London, staggered along Oxford-street to Regent's-circus, where he fell heavily, striking the back of his head against the kerb. He was picked up in a half-conscious state, taken to the police-station, and subsequently brought to the Middlesex Hospital. On admission, he was in a very muddled state of mind, and smelt strongly of drink. There was a small scalp wound, slightly to the left of the occipital protuberance; it did not extend to the periosteum. His pupils were regular and acting; his respiration and pulse natural; there was no symptom of any fracture of the skull. The stupidity of manner which was attributed to alcohol passed off after several hours, and for the next three days he lay quietly, perhaps drowsily, in bed. All this time he remained quite sensible, answered questions readily and intelligently, though in rather a subdued voice, and gave a very clear, though a most discreditable account of his recent proceedings. He looked pale, took very little of the milk and beef-tea diet to which he was limited, and complained of frontal headache and double vision. On the morning of December 17th, he was sick, complained of having passed a very restless night, and appeared to be on the verge of delirium tremens. Later on the same day the symptoms of delirium tremens became marked, and he was removed to the delirium ward. The urine voided this day was examined, and found free of albu-

³ Series III., vol. v., pp. 120, et. seq.

men. He was treated as all cases of delirium tremens under me are—viz., no opium was given, no undue or irritating restraint allowed, but enemata of two ounces and a half of strong beef-tea, with half an egg, were to be administered every three or four hours if he refused to take sufficient by the mouth. For fifty-eight hours he continued delirious, talking a good deal and having illusions. His other symptoms were subsultus tendinum, small and very compressible pulse, a moist, furred tongue, and clammy skin. He was very tractable, and neither violent or noisy. At the end of fifty-eight hours he slept soundly and for a long time. On the morning of December 22nd he was brought back into the general ward, and seemed quite well, though weak. So he continued, and on Christmas-day he went to the church service; but he complained of feeling rather drowsy, and of having pain in the back, for which a liniment was ordered by the house-surgeon. During the night the nurse noticed how restless he was. After a time, however, he fell asleep, and in the morning (Dec. 26th) it was impossible to wake him, and he was found to have passed his urine in the bed. At 10 a.m., when seen by the house-surgeon, he was lying in a comatose state, with unequal pupils, the right being widely dilated and the left very much contracted, neither pupil responded to light, and the conjunctivæ were insensible. The pulse was 100, very small and jerky. The skin was acting freely. There was slight twitching of both upper limbs; but it was very slight, and if more marked on one side than the other it was on the left. There was neither hemiplegia, paraplegia, nor facial palsy. At 1.30 p.m. he was in the same condition; the urine had all been passed into the bed, but two ounces of highly colored urine were drawn off by the catheter, and was found to be nearly solid on boiling. The pulse was 100, and very small; temperature 101° 6'. There was no œdema around the scalp wound, but a little purulent discharge from it. Firm pressure around the wound produced no symptom. At 7 p.m. one-eighth of a grain of pilocarpin was given by hypodermic injection, and in less than half an hour the patient was perspiring profusely. At 8.30 p.m. five grains of calomel were given in butter placed at the back of the tongue. He sweated freely all night, and the bowels acted several times, and abundantly. On the following morning (Dec. 17th) he was better; he answered when spoken to, and he could swallow beef-tea and milk. The pupils were unequal, as before, but the conjunctivæ were sensitive; there were less stertor, but otherwise the respiration and the pulse were the same. The temperature kept above 100° F. The urine was still very highly charged with albumen. The hot-air bath was employed at 1 p.m., and at 2.30 p.m. half a drachm of compound jalap powder was taken by the mouth. During the following day (Dec. 28th) and the early part of the day after (Dec. 29th) his general condition was about the same, but the quantity of albumen had diminished, and was now about half. Later on the breathing became more stertorous again; he could neither speak nor swallow, the pupils were still inactive and unequal, the right being dilated and the left contracted. At 9 p.m. the temperature shot up to 104° 2° F., and at 3.10 a.m. the following day (Dec. 30th) he died.

Autopsy.—The post-mortem examination was made by Dr. Fowler twelve hours after death. The following is an abstract of his report:—The body was well nourished. There was considerable post-mortem congestion. To the left side of the occipital protuberance there was a wound dividing the integuments, but not laying bare the bone. The wound was oblique in direction, one and three-

quarters of inch in length, and slightly irregular. The tissues around the wound were infiltrated with a little blood for about an inch in each direction. The tissue of the ventricles of the heart was pale but firm, but there was a considerable quantity of subpericardial fat. The mitral valve was thickened and fibrous at the edges, but competent. The aortic valves were competent; there were some spots of atheroma just above the attachment of the valves. The lungs were emphysematous, and there was a good deal of hypostatic congestion. The liver was moderately congested, and spleen was normal. The kidneys were large, and the capsules in places adherent; beyond swelling of the cortex, possibly from slight infiltration, there was no evidence of disease. The ureters were normal and the bladder healthy. On removing the calvaria, which was thick and very dense, no fracture could be found, nor was there any fracture of the base. The right half of the dura mater covering the convexity of the brain appeared somewhat distended. On reflecting this half of the dura mater blood-clot was found spread out beneath it. The clot was most abundant over the frontal bone and in the anterior fossa, but there was also a considerable quantity beneath the parietal eminence and over the occipital convolutions. The ascending frontal and the parietal convolutions were depressed and flattened. The blood was of mahogany tint, the concula were soft and adherent to the under-surface of the arachnoid covering of the dura mater. The source of the hæmorrhage could not be ascertained, but probably it was from a vessel behind the upper end of the right ascending parietal convolution. The dura mater separated easily from the bone. There was a small clot on the left side, immediately beneath the wound, which had compressed the occipital convolution over an area the size of a shilling. There was a small amount of extravasation within the meshes of the pia mater over the left half of the cerebrum. The venous sinuses contained some black clots. The arteries of the base were normal. The substance of the brain appeared normal, except that the depressed convolutions were pale. The left lateral ventricle was considerably dilated, the posterior horn reached three-quarters of an inch further backwards than the right ventricle. There was no blood below the tentorium. The cerebellum was normal.

In this case the scalp wound was not accompanied by a fracture of the skull, nor by lesion of the brain substance, nor was the effusion of blood most extreme beneath the seat of the wound, or the supposed source of the bleeding on the diametrically opposite point to the scalp wound, as might be expected if caused by counter-stroke. Moreover, the man was a drunkard, and had just previously to the injury undergone a prolonged debauch, whilst a few days subsequently he had suffered from an attack of delirium tremens. Then followed two or three days of apparent convalescence. These points might have furnished a strong case in favor of the theory that the injury had nothing to do with the cause of death, and that the extravasation occurred either before the injury, as the result of the congestion of drunkenness and excitement, or after it as the immediate effect of delirium tremens. Nor would the character of the blood-clots have disproved any of these suppositions. Their color and consistence corresponded, doubtless, with the date of the injury—viz., sixteen days before death; but the changes in

⁴ Possibly in this condition we have the explanation of the contracted left pupil, the distortion of the ventricle by traction keeping up irritation of the third nerve. The dilatation of the right pupil was doubtless due to pressure by the blood-clot, which flattened the cerebral hemisphere.

effused blood vary with the locality and with many other conditions, and are neither so regular nor so accurately known as to justify anyone in asserting that the age of the clots could not have been eighteen, twenty, or even twenty-five days on the one hand, or ten or twelve days only on the other. The late Dr. Taylor exposed the fallacy and danger of relying too much on the state of the blood as a means of asserting the length of time it has been effused. Two men were tried at Derby in 1859 for manslaughter. Within fourteen days after the assault the injured man was convalescent, but in four weeks more he was dead. The prisoner's counsel asked the witness—"I can produce evidence to show that deceased fell down some steps into a cellar, upon his head, three weeks before his death. Do you not think it more likely that death was the result of this fall rather than of the beating three weeks prior to the fall?" The surgeon at once said "Certainly not; there could not have been the effusion of lymph I describe after an accident in so short a space of time as three weeks." As Dr. Taylor remarks, reasons justifying such a strong opinion were not forthcoming, and he goes on to prove by another case that there was nothing in the description of the clot in question to show that the effusion had taken place more than three weeks before death.* This and other cases quoted by Dr. Taylor warn us how unwise it is to dogmatize on this subject. But, it might be urged in opposition, there was no Bright's disease, no anemia, no disease of the vessels of the brain or its membranes, in this man; and, though there was no fracture of the skull and no bruising of the brain, there was a little blood effused beneath the seat of the scalp wound, and the most extensive effusion was in the situation where it would be looked for if caused by contre-coup. Moreover, it might be added, there was frontal headache and double vision. Such points should, of course, be allowed their proper weight, for they are of considerable significance in making up one's mind as to the more probable cause of death. But they do not dispose of the facts (1) that blood poisoned by alcohol may produce much the same effects as Bright's disease—e.g., the convulsions of renal disease, and the epileptiform convulsions of intoxication;⁶ and (2) that the prolonged toxic effects of alcohol may produce a diseased condition of the brain and its membranes such as will lead to the occurrence of epilepsy, delirium tremens, or hæmorrhage even during the periods of comparative or entire abstinence from drink.

What I have desired to point out by these remarks and by this somewhat extraordinary case is:—1. That spontaneous effusions into the cavity of the arachnoid—i.e., effusions of blood from disease or excitement—are very often not distinguishable from traumatic effusions. 2. That post-mortem examination does not always explain the cause or the source of the effusion, and that the state of the blood-clot is only a very rough test as to the age of the effusion. 3. Extravasation of blood between the dura mater and bone, as also extravasations beneath the visceral arachnoid, accompanied by brain bruising, are almost certainly traumatic, whether fracture co-exists or not. Extravasations into the substance of the brain and into the ventricles are almost certainly spontaneous when no fracture and no brain bruising co-exists, and are probably so even when fracture without bruising of the cerebral surface is found. 4. Spontaneous effusions may occur without there being any naked-eye evidence of disease of the cerebral

or meningeal vessels. 5. Spontaneous effusions into the arachnoid cavity from disease or excitement have occurred as early as the twelfth year of life, and at all ages subsequent to puberty. Inter-arachnoid hæmorrhage occurs at any age from violence. 6. In slight injuries to the head, such as small scalp wounds without fracture of the skull, or bruising of the surface of the brain, the surgeon should be extremely cautious in attributing inter-arachnoid extravasation to a blow, and more especially when, as in the above case, the injured person is of intemperate habits.

CLINICAL OBSERVATIONS ON THE TREATMENT OF ENLARGED TONSILS.

By GORDON HOLMES, M.D.

1. *Excision.*—That excision is the most fitting remedy for enlarged tonsils is a proposition from which few authorities or none would now be found to dissent. The theory, however, that removal of the tonsils has some adverse effect on the generative system has gained some currency amongst practitioners. Those who practice the throat speciality will scarcely attach any importance to this hypothesis, as they have the opportunity of observing numerous cases of females who have borne large families, although the tonsils were excised in youth.

The condition of the tonsils at the time of operating is a point which deserves attention. As a rule, when the patients first present themselves, the organs are in a state of acute or subacute inflammation, which is the immediate cause of treatment being sought. Under these circumstances, some practitioners are in the habit of operating at once, whilst others wait until the tonsils have regained their ordinary condition of indolent chronic enlargement. In order to decide this question, the arguments to be drawn from clinical observation are rather in favor of delay. It is no doubt well for the patient to be relieved at the soonest from the diseased glands, and the excision, with the attendant hæmorrhage, may abridge, or render abortive an attack of quinsy. If, however, the tonsillitis is very acute, the pain of the operation may be excruciating, and it may even be difficult to open the mouth wide enough for the accurate introduction of the instruments. But the most important consideration is that after the inflammation has subsided, and a few weeks have been employed in general tonic and local astringent treatment, the tonsils may return to nearly their natural size. Of course should the history of the case indicate clearly a permanent hypertrophy, we need not hesitate to operate immediately when other circumstances are favorable. It is, indeed, by no means uncommon to see even cases of mild subacute or chronic tonsillitis, in which a considerable swelling undergoes spontaneous involution in the course of a month or two, according as the general health improves. Such instances are very likely to mislead the practitioner into the belief that a cure has been wrought by the aid of some really impotent local application. It is also interesting to observe that in a series of such attacks, where the subsequent involution is always less and less complete, we can perceive the origin of chronic tonsillar hypertrophy. And most probably there is no other way in which the disease arises, unless in those cases where the enlargement is apparently congenital.

* Taylor, A. S., Medical Jurisprudence, 1865, p. 530.

⁶ Vide Dr. Robertson's evidence in a recent trial for murder at Glasgow.

With respect to the method of operating, the tonsillotome has almost superseded the bistoury and tenaculum, owing to the ease and rapidity with which it can be used, and the little suffering it causes the patient. The rare case of a tonsillar calculus alone remains in which the tonsillotome is inapplicable. The instrument known as Physick's is preferred by some, that of Fahnstock by others, the majority; both models being of American invention. Physick's pattern has the advantage of allowing more force to be applied in fixing it firmly on the tonsil, as it is grasped by a stout handle, whilst the convex cutting-blade can also be pressed down with great power by the thumb. Fahnstock's, on the other hand, is an instrument to be employed with dexterity rather than force, as it is manipulated by the thumb and first two fingers only, each of which is accommodated with a separate ring. It is, however, a much surer instrument than Physick's, which often fails to excise the tonsil, even in the hands of the most practiced operators. This is mainly due to the aptness of the convex blade, which enters at one point only, to press the tonsil outwards, and glide over or merely lacerate its surface, even when sharpened to perfection. The tonsil is, in fact, often very gristly, and requires to be jammed very firmly against the blade in order to be cut directly through. But the lunated edge of Fahnstock's cutting ring is much less likely to swerve from the straight course, as it begins by being in contact with the whole surface to be incised, whilst the organ is steadied and drawn into the tonsillotome by the transfixing prongs.¹ As Fahnstock's instrument is therefore almost certain never to miss the tonsil, it is more under the command of the operator, so that a larger or smaller portion can be removed according to the requirements of the case; whereas in using Physick's, owing to the necessity of fixing it as deeply and firmly as possible over the tonsil, the amount to be taken must mainly be left to chance. For the practitioner who seldom has occasion to excise the tonsils, Fahnstock's is decidedly the model to be recommended. In all cases it is advisable to support the tonsil during the operation from the outside of the neck, either by the hands of an assistant or by grasping the throat in a fork formed by the left thumb and forefinger of the operator.

As regards hæmorrhage after tonsillotomy, it is usually very trifling and ceases spontaneously in a few minutes, or after gurgling with cold water. In rare cases (probably about 1 per cent.) it is troublesome and must be controlled by ice and strong styptics. Considered in this relation the tonsillotome is safer than the bistoury, as the dragging of the tenaculum displaces the parts so that the knife may inadvertently cut deeper than intended by the operator.

2. *Caustics*.—Although excision is the standard remedy, cases are constantly met with in which the patient or his relatives, if a child, steadfastly refuse to permit the performance of the operation. Frequently also it happens that the enlargement is not so pronounced as to render the excision strictly necessary. It is of great importance therefore that we should be in possession of some mild measures, which, aided by time, can effect a reduction of the tonsils. For the purpose astringents (such as strong solutions of perchloride of iron, chloride of zinc, etc.) or caustics are our only resource; but the former, however useful in promoting spontaneous resolution in cases of temporary subacute engorgement, are totally powerless in the face of a true hypertrophy. Hence the only means that can be adopted with any clear prospect of success is to

destroy small portions of the tonsils in slow succession by repeated cauterizations carried on for a lengthened period. This object is generally carried out by the application of solid nitrate of silver, chloride of zinc (in the stick), Vienna paste, London paste,² or the galvano-caustic to a limited area of the surface of the tonsil every two or three days. Of these remedies the nitrate of silver is very valuable when the superficial substance of the gland is in a softened and raw state, as it can be rubbed freely over the whole organ, usually without causing any suffering to the patient; but it is of slight avail in reducing the volume of the toughened mass of connective tissue which generally constitutes the bulk of the permanently enlarged tonsil. Nor can it be said that the stronger caustics are much more potent in this way, for they can only be used in this position so as to destroy very minute portions at a time, and hence the progress is mostly so slow and tedious that few patients will persevere until positive results have been attained. If any exception can be made to this statement, it must be in favor of the galvano-caustic³ (a small loop of wire raised to a white heat by electricity as soon as placed in contact with the surface to be cauterized), for it kills immediately the part touched and leaves a clean ulcer, which soon heals almost unfelt by the patient. On the other hand, the London paste, etc., often give rise to considerable congestion round the sloughing point, attended with aching and pain on swallowing for many hours.

There is, however, another method, very much more effective, of applying the common caustics to the tonsil, which appears to have remained hitherto unnoticed. The tonsil, as the anatomist knows, is permeated by several rather large channels around which the follicles are collected, opening on the pharyngeal side of the gland, whence its characteristic cribriform aspect. Their orifices, about seven to fifteen in number, are sufficiently evident to be counted on the healthy tonsil *in situ*, whilst in the hypertrophied condition these lacunæ increase greatly in calibre and depth, and can be ascertained by a probe to vary from one-eighth of an inch to half an inch in length, with a diameter capable of admitting a style of ordinary size. These observations, then, afford a valuable indication for treatment: for through these natural canals a way lies open for us to attack the heart of the gland in a most efficacious manner with our caustics. Thin, pointed sticks of nitrate of silver or chloride of zinc can easily be pressed into the lacunæ and worked round for a few seconds. Small sloughs are thus formed which are soon discharged, and in the progress of this treatment the tonsils are hollowed out in one direction whilst being contracted into much smaller bulk by the subsequent cicatrization in another. Two or three channels in each tonsil can be cauterized daily or on alternate days, and we can thus act on a comparatively large surface whilst causing but slight external soreness and little or no suffering to the patient. In practicing this method, although the stronger caustics may be used, I do not think it will be necessary to have recourse to anything more potent than nitrate of silver, which acts much more effectually on the more tender internal structures of the tonsil than when applied to the comparatively callous pharyngeal surface.

Finsbury-square, E.C.

² Equal parts of powdered unslaked lime and caustic soda made into a paste with water as required (Mackenzie).

³ Now coming into general use, chiefly owing to the advocacy of Dr. Capart, of Brussels.

¹ The prongs are sometimes fitted to Physick's model.

A CASE OF INTRA-ORBITAL ANEURISM

FOLLOWING FRACTURE OF THE ANTERIOR FOSSA OF THE BASE OF THE SKULL AND MENINGITIS; LIGATURE OF THE COMMON CAROTID SIX DAYS AFTER ACCOUCHEMENT; EXTIRPATION OF EYEBALL; RECOVERY.

By WALTER E. LLOYD, L.R.C.P. Ed. and L.F.P.S.G.

Cases of intra-orbital aneurism are of somewhat rare occurrence. Statistics show that the majority of the cases that do recover are those treated by ligature of the common carotid. A case recently reported by Dr. Wolfe, of Glasgow, which had been operated on by that devoted surgeon, the late Dr. Foulis, adds another to the list of successful cases treated by this method. Although the case I am about to relate differs somewhat from Dr. Wolfe's, happily the same result was secured. In my case the aneurism was first intra-cranial, and then, progressing gradually through the sphenoidal fissure, became intra-orbital. The history of the case shows it to have been entirely traumatic.

Mary Jane W—, aged twenty-nine, the wife of a journeyman baker, on July 21st, 1881, was driving in a two-wheel cart with her husband, delivering bread in the country; while returning home through the village of Long Ashton the horse fell down, and the man, his wife, and a child were all thrown out on to the road; the man and the child were uninjured, but the woman pitched on to the left side of her head. I happened to pass the scene of the accident about five minutes after, and was requested to attend to the injured woman. She had been lifted into the cart and I found her in a semi-conscious condition, bleeding slightly from the nose. I ordered her to be at once removed to her home, and shortly after went there and was able more thoroughly to examine her. I found her in bed lying on her back with symptoms characteristic of concussion. When spoken to loudly she opened her eyes and attempted to answer, but was unable to do so. The bleeding from the nose still continued; there was subconjunctival ecchymosis of both eyes, but most marked on the left side; the pupils were normal and acted when stimulated by light. I ordered her to be kept on milk and beef-tea. I found her to be six months pregnant. The next morning symptoms of meningitis appeared, and by the evening (twenty-four hours after the accident) she was in a state of violent delirium, the assistance of three or four persons being required to keep her on the bed. I ordered the head to be shaved, and an ice-cap applied. The bleeding from the nose had ceased, but the subconjunctival vessels were very much gorged with blood, those of the left side being somewhat more so than the right. The delirium continued for three days, when she gradually recovered consciousness, and from that time she made good progress. I kept her in bed, and after about six weeks it was noticed that the left eyeball was becoming more prominent. She found the sight was going from the left eye, and complained of a loud whirring, "like the noise of a mill," in the left ear, also of deafness on the same side. It became at length evident that these symptoms were due to an intra-orbital aneurism. On applying the stethoscope, a loud bruit was heard over the frontal and left temporal bones, and there was distinct pulsation of the left eyeball, both of which ceased when the left common carotid was compressed.

Now arose the question of treatment, and the complication of her being seven and a half months

pregnant was a grave one. In consultation with two of my surgical friends, it was decided that it was best not to attempt an operation until after accouchement, but to keep her in bed, give ten-grain doses of iodide of potassium three times a day, and when the labour came on to deliver her as speedily as possible, so as to avoid the consequences of straining during labour; this was the treatment adopted up to the time of her confinement.

On Oct. 14th I was sent for at 9 A.M., and attended immediately. I found she had been in labour about two hours, the os uteri was dilated as large as a crown, the pains were forcing, and as I found the head did not make speedy progress, I at once applied the long forceps, and delivered her in a few minutes of a remarkably large living male child. The prominence of the eyeball was not affected by the labour.—15th: Doing well, the condition of the eyeball not altered at all.—16th: Doing well as regards the confinement, but complains of great pain in the head, and that the noise is much louder than it has been hitherto; the conjunctiva is much more injected, and the eyeball more prominent. Ordered iodide of potassium and bromide of potassium, ten grains of each, every four hours.—17th: The protuberance of the eyeball much increased, as is the œdema of the conjunctiva. She cannot sleep, the pain and noise in the head are also increased.—18th: All the symptoms are still more aggravated. Pulsation very marked, and the eyeball still more protruding; the sight is now quite gone from this eye.—19th: The prominence of the eyeball still much more increased, and the œdema of the conjunctiva much more marked, projecting one-eighth of an inch beyond the cornea; cannot distinguish light from dark. Says the pain in her head will drive her mad. Pulse weak, about 60; temperature normal; going on well as regards the confinement. I was sent for hurriedly at 8 P.M., as it was thought she was dying. My friend, Mr. W. H. Harsant, surgeon of the Bristol Royal Infirmary, saw her in consultation with me, and we decided that the only chance of saving her life was to ligature the common carotid. She was then very faint; anxious expression of countenance. Pulse hardly perceptible. Ordered brandy, and the following mixture—tincture of opium, ten minims, with compound spirit of ammonia, twenty minims, every four hours. Owing to the extreme delicacy of the operation, and the many difficulties which presented themselves, there being no gaslight and having no assistants, etc., we postponed the operation until the following morning, hoping also that she might be better able to take the chloroform.—20th: Her condition is slightly improved, the pulse being somewhat stronger. Chloroform having been administered by Mr. Harsant, whom I cannot sufficiently thank for his very valuable assistance, I proceeded to ligature the common carotid. Making an incision three inches and a half in length along the anterior border of the sterno-mastoid, and carefully dissecting, I divided the different layers of tissue on a director. There was no special feature in the operation, except that the artery was overlapped by the internal jugular vein, which had to be drawn aside by a retractor, the carotid being found directly underneath it. The needle, being carefully passed from without inwards, was then threaded with a stout carbolized catgut ligature, which having been tied and the ends cut off short, the wound was brought together with six horse-hair sutures, and covered with boracic lint. I was most ably assisted by Mr. W. A. Jones and Mr. H. M. Powell, students of the Bristol Medical School. During the progress of the operation there was very slight hæmorrhage, one small vessel having to be

secured by torsion. 7 P.M. (four hours after the operation): Frequent vomiting from the chloroform. Ordered ice to suck. Says she feels much better; the pain in the head is much less, and the whirring noise is gone. The oedema is already much less, the pulsation has disappeared, and the bruit cannot be heard. She says that now she can see me quite distinctly.—21st: Has been vomiting during the night. The bruit is slightly audible; there is no pulsation. She says she has been much relieved by the operation, and feels quite different. The wound is looking healthy, but there is some pain at the top of the head (neuralgic). Pulse 80; temperature normal.—22nd:—The vomiting has ceased. She still complains of the neuralgic pain. About three drops of pus came from the lower end of the wound when I dressed it to-day, but it is looking healthy. Pulse and temperature normal.—23rd: Mr. Harsant saw the case with me to-day. There is a most marked improvement; the protrusion of the eyeball is rapidly receding, and the fold of the eyelid is seen when the eye is open; the sight is perfect, the oedema of the conjunctiva is much less, and she is able to use the muscles of the eye, and rotate it on any axis. The wound is looking healthy, but, as there is some pus coming from the lower end, I removed the lowest suture, and about a drachm of pus exuded. Otherwise she is doing remarkably well. The bruit is still slightly audible.—28th: The oedema of the conjunctiva very much less. I removed the last three sutures from the wound, which has healed, except at the lower end, from which the pus escapes. Ordered fish diet. She says the whirring noise has almost gone. She was quite deaf on the left side before the operation was performed, but can now hear quite distinctly on that side. The prominence of the eyeball has most markedly decreased. There is now no pulsation, and the bruit is hardly perceptible. The wound completely healed after a few days.

The progress of the case has been somewhat remarkable. At times there has been acute pain in the head, referred to the back of the left eyeball, relief from which could only be obtained by large doses of opium. The sight of the left eye has become gradually destroyed, the crystalline lens has become opaque and the eyeball pushed forward by what appears to be a large organized blood-clot; the bruit is still heard very distinctly, but, whereas before the operation it was heard loudest over the orbit and temporal fossa, it is now heard loudest over the mastoid process and the occiput. The sight of the right eye being threatened by the condition of the left, I determined to extirpate the left eyeball.

July 6th: Mr. Harsant having kindly given chloroform, I extirpated the eyeball. It was with great anxiety that I commenced this operation, fearing that during its progress I might possibly cut into the aneurism and the patient die from hæmorrhage. Happily my fears were not realized; there was hardly any bleeding. After removing the eyeball I passed my finger carefully into the orbit and could feel a firm but somewhat elastic mass at the back. The wound rapidly healed. The patient has been into the country and has returned home in perfect health, and able to perform her domestic duties; she is about to have an artificial eye in the place of the one removed.

I believe this to be the first case reported in which the common carotid artery has been ligatured six days after a woman's confinement. Although the operation was of so grave and complicated a character the result clearly justified the means, as this woman's life was undoubtedly saved by the operation. In conclusion, I would call at-

tention to the rapid healing of the wound, notwithstanding the fact that the operation was not performed antiseptically.

Bristol.

A CASE OF EXTREME CYANOSIS IN AN ADULT, PROBABLY OF CONGENITAL ORIGIN¹.

By JUDSON S. BURY, M.D., B.S. Lond.,

Honorary Assistant Medical Officer to the Clinical Hospital and Dispensary for Children, Manchester.

MARY F—, aged twenty-one years, was quite well during infancy and childhood, the only ailment she ever had was an abscess in the thigh. Her mother states that she was not a delicate child, was not more easily tired than other children, and did not differ in color or in any other respect from a healthy child. The blueness set in suddenly about two and a half years since. The patient had "hurried a good deal" and felt pains in the chest and back and a choking sensation, and the woman with whom she worked remarked that "she was as blue as a whimberry." The blueness disappeared the next day but returned in a few weeks, and has since persisted. Menstruation began shortly after the first appearance of the cyanosis. When the patient was between nineteen and twenty years of age she was regular for the first year; then the catamenia stopped for about nine months. They now occur regularly, but are very scanty. There is no family history of rheumatism, and the patient had never had pains in her limbs or other symptoms suggesting a rheumatic diathesis.

Present condition.—Patient is of short stature, being about 4 ft. 7 in. Facial expression somewhat dull; skin muddy and dusky, the lips are blackish-blue; the conjunctivæ injected and of a light-claret color; nose and cheeks purplish; the tongue, inside of the mouth, and throat present a dark-purple, congested appearance; the ends of the fingers and toes are clubbed and livid; extremities cold; no oedema; the urine is high-colored, deposits urates, and contains a trace of albumen. On inspection of the chest, a distinct bulging is visible; it involves the second, third, and fourth left rib cartilages; there is some tenderness over the sternum. The jugular veins are not distended, but there is a distinct pulsation of the carotid arteries. The heart's impulse is diffused and heaving; it is felt in the third, fourth, and fifth spaces, as far out as the anterior border of the left axilla, but it is not felt near the sternum nor is there any epigastric pulsation. The maximum point of the impulse is in the fifth space in the nipple-line; no thrill. The cardiac dulness is much increased, and laterally rather than vertically, extending from about one inch to the right of the sternum to almost the middle of the left axilla; the third rib marks the upper limit of superficial dulness, though the first two spaces are higher pitched than those on the right side; the sixth rib is the lower limit. On auscultation a high-pitched, systolic, whistling murmur is heard at the base, of maximum intensity over the first piece of the sternum; it is well conducted down this bone, being also well heard at the right sterno-clavicular articulation, and faintly in the carotids. A vertical line from the middle of the left clavicle marks its extreme left limit, and the murmur is gradually lost as the stethoscope is moved towards the apex; it is not heard behind; the sounds at the left apex are quite pure. The second sound is accentuated

¹ Case shown at the Medical Society, Manchester, October 4th, 1882.

over the pulmonary cartilage, and is louder than at the aortic cartilage. The pulse is regular in rhythm, but not quite regular in force; it is equal on the two sides, and is felt in the femorals and in other arteries.

Remarks.—The striking feature of the case is the comparatively sudden onset in an adult of intense and permanent cyanosis, unpreceded by any illness, and found to be associated with extensive heart disease. If the latter were the result of endocarditis entirely acquired after birth, we should expect to have marked signs of engorgement of the general venous system; indeed the absence of dropsy alone points strongly to some congenital malformation of the heart, and also proves that cyanosis cannot be completely explained by the theory of venous congestion. The bulging of the chest may be taken as an indication that the enlargement of the heart occurred at an early period, when the chest walls are soft and yielding. By far the commonest cause of congenital cyanosis is contraction of the pulmonary artery as a result of foetal endocarditis; the first consequence of this contraction is hypertrophy of the right ventricle, the second a permanent communication between the two sides of the heart; and if stenosis is extreme it may prevent the closure of the ductus arteriosus. Thus there is compensation for the strain on the right ventricle; the venous blood passes into the aorta and is conveyed to the lungs either by enlarged bronchial or other arteries, or by a dilated ductus arteriosus. These safety valves prolong life and diminish or prevent cyanosis. In contraction of the pulmonary artery the duration of life varies directly, the cyanosis probably inversely, with the degree of patency of these foetal passages. It is now indeed well established that the mere intermixture of arterial with venous blood is not sufficient to produce cyanosis, the essential element for this condition being, as Dr. Lewis Smith puts it, the hindrance to "the free and regular flow of blood to, through, or from the lungs." The physical signs in the case before us are somewhat complicated. In pulmonary stenosis we expect indications of hypertrophy and some dilatation of the right ventricle, together with a basic systolic murmur of maximum intensity at the junction of the third left costal cartilage with the sternum, conducted towards the left clavicle and not audible in neck arteries. In the patient the murmur is loudest at the top of the sternum, is conducted to the right as well as to the left, and is heard in the carotids. There is increase of dullness to the left as well as to the right, and there is no epigastric pulsation, but a heaving impulse in the left mammary region. Most of these signs point to disease at the aortic orifice rather than at the pulmonary; but this as a result of foetal endocarditis is very rarely met with, not because (as Rauchfuss points out in Gerhardt's Handbuch) the aorta is less frequently affected with endocarditis than the pulmonary artery in foetal life, but on account of the very short duration of life, only one-eighth of the cases collected by Rauchfuss survived the second week of life, only one case the first month. Dr. Sansom, in a lecture reported in the *Medical Times* for 1879, relates a case of congenital stenosis of the pulmonary artery where the basic murmur had an aortic conduction. Although the aorta after death was found to be quite normal, he thinks that this was due to the coexistence of a hæmic murmur. Dr. Peacock says that the septum of the ventricles being usually defective when there is a considerable contraction of the pulmonary artery, "the aorta derives its supply of blood from both ventricles; and if so, a systolic murmur may probably be produced by the meeting of the

two columns of blood in the ascending aorta, which may modify the signs observed.

In spite, then, of aberrant physical signs, it seems probable that the origin of the pulmonary artery was affected with endocarditis in foetal life, that the effects of its obstruction were compensated for by the persistence of communication between the two sides of the heart, and, perhaps, also by a patent ductus arteriosus; and, according to Rauchfuss, the loud second sound at the pulmonary cartilage would favor a patent duct. But about puberty, as the body became more developed and the volume of the blood greater, the insufficiency of the heart first made itself apparent. It is possible, too, that a fresh endocarditis was lit up about this time, and affected the aortic valves, for, as Dr. West has pointed out, congenital malformations of the heart predisposed to inflammation of the valves.

Manchester.

CASE OF ACUTE RHEUMATISM, OCCURRING IN A NEWLY-BORN INFANT, TREATED WITH SALICYLATE OF SODA.

By F. ERNEST POOCK, M.D.

ON May 25th I was called to see Mrs. A—, who had been ill for two days. I found her suffering from acute rheumatism, with a temperature of 106.5°. She was pregnant with her second child, and, as far as I could gather, within about a month of her confinement. I ordered twenty grains of salicylate of soda every hour for six doses, and then every two hours. On Tuesday morning, about thirty hours after seeing her for the first time, the rheumatic pains left her entirely, and labour pains came on, resulting in about four hours in the birth of a sturdy male child, who appeared perfectly healthy. The rheumatism returned immediately the child was born and she could not bear it put to the breast. The milk was dispersed by belladonna, and Mrs. A— made a fair recovery in about five weeks, but unfortunately with considerable valvular mischief.

The child was a very cross one, and cried very much, which the nurse and the mother attributed to flatulence and want of food. However, dill-water, aniseed, etc., having no effect, I was sent for about twelve hours after the birth. The child was decidedly feverish, with a moist skin and an acid smell about him. I noticed that he appeared to cry more loudly whenever his right arm was moved. On removing the dress, his right shoulder and elbow were found reddened, and on moving either joint he cried lustily. On using the thermometer I found his temperature 103.5° and his pulse 170, as accurately as I could count it. Under the circumstances, it occurred to me that he might have the rheumatic poison in his blood, and that in fact I had to do with a case of congenital rheumatic fever. As Mrs. A— was unable to nurse him, and we thus could not give him any medicine per matrem, I determined to administer the salicylate in a direct form. Four grains were given in a little sweetened water every two hours for six doses. The pain then seemed less, and it was given every four hours. However, the restlessness returned, and the temperature was found to have risen to 104°, and it was therefore continued every two hours for four doses more, and then the interval increased to three hours. By this time (about forty hours from birth, or twenty-eight from the commencement of the salicylate) the temperature was reduced to 101° and the pulse to 140. In another twenty-four hours the interval between the doses was increased to four hours, and in another

day to six hours or three times a day. When about 180 grains had been taken, and the child was nine or ten days old, the drug was stopped for twenty-four hours, but given again at the end of that time in four-grain doses two or three times a day as occasion required for a fortnight. After this a tea-spoonful of cod-liver oil was rubbed into the skin twice a day for three weeks, when the child appeared perfectly well. The temperature had gradually and steadily diminished since it had risen to 104°, which was when the child was thirty hours old, down to the eighth day, when it was normal, and never rose after. Nestle's milk food was given as sustenance, and a few grains of mercury with chalk as occasion required. I was unable to detect anything abnormal about the heart sounds all through.

This is, as far as I know, a unique case, and I trust it will be of interest to the profession. It seems to show that the salicylate does not deserve quite all the hard things that have been said and written about it; and that even in the case of a newly-born infant it may be pushed almost to an extreme without producing the head symptoms which have so often been laid to its charge. May not these latter, in many reported cases, have been due to the rheumatic blood circulating through the brain, and not to the drug?

St. Mark's-road, North Kensington.

THE FIRST FIVE YEARS' WORK AT THE LIVERPOOL SEAMEN'S DISPENSARY FOR VENEREAL DISEASES.

By FREDERICK W. LOWNDES, M.R.C.S. Eng., and
ARMAND BERNARD, M.B. Dub.,

Surgeons to the Dispensary and to the Liverpool Lock Hospital.

THAT merchant seamen suffer severely from venereal diseases is too well known to require proof. It is also well known that it is among them the advertising venereal quacks find many victims. These two circumstances induced the committee of the Liverpool Sailors' Home, upon our suggestions, to open in February, 1877, a self-supporting dispensary, in connection with the home, for the treatment of venereal diseases among all seamen in Liverpool, whether British or foreign, and whether inmates of the home or not. It was decided from the commencement to limit the practice of the dispensary to cases of venereal disease, and that the dispensary should be self-supporting, each patient paying one shilling for each attendance, receiving for this advice and medicine. The result of the five years' working, ending December 31st, 1881, will be of interest, and may be an encouragement to those who advocate self-supporting dispensaries. The lock hospital here has twenty-five beds for male patients, which are constantly full; there is no out-patient department at it nor any of the general hospitals, except the Stanley Hospital, which is a long way from the Sailors' Home. The nearest general dispensary (the South) is also some distance off, and the hours of attendance are very inconvenient ones for sailors; hence the dispensary supplied a want without adding to free medical charities or doing any injustice to the latter. It also brought medical advice and medicine within easy reach of the sailors, whose nearest advisers had hitherto been the advertising quacks. We have restricted the practice of the dispensary as much as possible to men before the mast, though we occasionally see stewards, cooks, boatswains, carpenters, etc. Suitable premises were found contiguous to the Sailors' Home, and the dispen-

sary was opened on February 26th, 1877. The following table shows the results:—

Year.	Patients.	Attendances.	Remarks.
1877	847	2363	Only ten months.
1878	1002	3246	Whole year.
1879	853	2823	Ditto.
1880	944	3512	Ditto.
1881	848	3276	Ditto.
Total ..	4494	15,220	—

For the first year we were unable to keep so accurate a register of cases as we could have wished; but since Jan. 1st, 1878, a most careful and, so far as is possible, a most accurate register has been kept, from which we are enabled to give the following summary:—

	1878.	1879.	1880.	1881.	Total.
Simple sores.....	226	173	229	205	833
Gonorrhœa.....	364	321	330	294	1309
Gleet.....	200	169	184	136	689
Primary syphilis...	112	101	115	107	435
Secondary syphilis.	95	83	79	96	353
Tertiary syphilis...	5	6	7	10	28
	1002	853	944	848	3647

Of the total of 3647 cases, 816 were case of syphilis, or 22·374 per cent.

Simple Sores.—Our diagnosis has often to be made on the eve of a sailor's departure to sea; hence it is possible that some of these might eventually prove to be the initial manifestation of syphilis. As a rule these simple sores healed up readily, especially with iodoform ointment. Merchant seamen are by no means cleanly in their person, a fact of which we have daily evidence. Hence we have many cases of balanitis, and simple sores are much aggravated by this want of cleanliness.

Gonorrhœa and Gleet.—For these the old copaiba mixture still holds its own, and with a few exceptions answers very well. In obstinate cases an injection of sulpho-carbolate of zinc, two grains to the ounce, is ordered as well. Our chief difficulty is to induce patients to abstain from intoxicants until after they are thoroughly cured.

Bubo.—These occur very frequently among sailors in conjunction both with simple sores and gonorrhœa. As a rule, after being opened they heal rapidly, especially if this has been done in good time. But in many cases there has been much delay, especially when the disease has been contracted immediately before sailing; in these cases there is much undermining and disorganization of the parts, and the healing process is much retarded. In these cases, again, we have found iodoform most beneficial, sometimes in the form of powder dusted over the part, or as an ointment (forty grains to the ounce) with or without operative treatment.

Syphilis.—The practice of this dispensary affords favorable opportunities for observing the variable periods of incubation, which average from fourteen days to eight weeks. It is true that we cannot place absolute reliance on the statements of our patients, especially as, with the uncleanly habits already noticed, an indurated sore might easily escape notice amidst a mass of smegma. On the other hand, there is the fact that in the case of sailors this incubative period can be determined with more accurate data than in the case of lands-

men. A seaman discovers that he is infected some weeks after sailing, and therefore some weeks after the possibility of impure sexual intercourse. In a certain number of these cases, the patients being of superior intelligence, we have been able to ascertain the period with great exactness. Primary ulcers are generally situated on the prepuce or in the furrow between the prepuce and the corona glandis, involving frequently both these parts. Induration is generally well marked, and especially in those cases where the disease has been in existence for some weeks without any treatment. In the treatment of syphilis we find it necessary to administer mercury in a very mild form and in small doses, the reckless habits of seamen in exposing themselves to wet and cold, their too frequent intemperance and impaired constitutions, making it imperative to exercise great caution in the administration of this drug. We require them to attend every second day, and supply them with sufficient medicine to last two days. A pill containing two grains of grey powder with three of Dover's powders, made up with confection of roses, is the form we mostly prefer. We also give the biniodide of mercury in mixture, and sometimes mercury by inunction. Our chief difficulty is the short time allowed us by the patients' stay in port, many men proceeding to sea in an unfit state, as will be seen further on. To those who are fit to proceed to sea, but require a continuation of the treatment, we give extra medicines, with every necessary precaution. Our experience here confirms that of most workers in this special line of practice—viz., that syphilitic diseases are most amenable to treatment if taken in proper time, and if the treatment be not interfered with by any untoward circumstances.

The following extracts from our register afford melancholy proofs of the unseaworthy state of many sailors; these being only a few out of many which might be given, and only an infinitesimal proportion of the probable whole number of seamen leaving English ports infected with venereal disease:

March 15th, 1878.—T. D.—. Phimosi ulcers of prepuce, and indurated glands. To sail next day.

April 23rd.—C. W.—. Indurated ulcer of corona, indurated glands; a very severe case. Going to sea in the morning.

April 27th.—C. W.—. Indurated sore of corona, indurated glands and secondary eruption. Sails on the 4th May.

May 10th.—J. P.—. Large indurated sore of corona, indurated glands. Going to sea in the morning.

May 14th.—J. H.—. Papular eruption on back, loins, arms, forehead, and legs. This man is saturated with syphilis. Going to sea to-morrow.

May 30th.—G. G.—. Ulcer of prepuce, gonorrhoea, suppurating bubo. Arrived to day; unable to work last five days; sent to lock hospital.

Nov. 6th.—J. C.—. Syphilitic disease of testicle. Going to sea next day.

Dec. 4th.—J. J.—. Orchitis and gonorrhoea. Going to sea next day.

Dec. 18th.—J. Q.—. Suppurating bubo; ulcers of prepuce. Just come from sea. Opened bubo.

Dec. 19th.—J. F.—. Indurated sore of prepuce; indurated glands; secondary eruption; disease of three months' standing. Going to sea on the 21st inst.

Jan. 13th, 1879.—T. L.—. Phimosi; ulcers; suppurating bubo. Going to sea. Seen subsequently on March 20th. A very bad case of syphilis.

July 6th.—J. B.—. Paraphimosi; ulcers of prepuce; indurated glands. No room in lock hos-

pital; refused admission to workhouse. Compelled to go to sea.

In some cases we have been able to induce men not to go to sea, but to remain ashore until cured.

As regards the financial success of the dispensary, it will suffice to say that from the very commencement it has paid its way, the receipts from patients enabling us to pay rent, taxes, drugs, dispenser's salary, etc., and to leave a small and we hope increasing balance for honoraria, in accordance with the original rules. The members of the Committee of the Sailors' Home have individually and collectively shown us the greatest kindness and assistance, and the same remark applies to the energetic and indefatigable secretary, Mr. Thomas Hamner.

Liverpool.

THE DIFFERENTIAL DIAGNOSIS BETWEEN HYSTERICAL PARALYSIS AND POLIO-MYELITIS ANTERIOR.

By A. HUGHES BENNETT, M.D.,

Physician to the Hospital for Epilepsy and Paralysis, Regent's Park; and assistant-Physician to the Westminster Hospital.

In the experience of every practitioner there must have occurred cases of paralysis in women upon which he has been called upon to decide whether the affection was due to serious organic disease of the nervous system, or to that more protean disorder to which we give the name of hysteria. In many such instances there is often the greatest possible difficulty in arriving at a satisfactory conclusion, and the perplexity of the medical attendant is proportionate to the responsibility he assumes in expressing an opinion, and the important issues upon which his verdict depends. That grave errors in judgment on this complicated problem have frequently been made, must be within the knowledge of all, resulting in misfortune to the patient, discredit to the profession, and a triumphant harvest to the charlatan.

Polio-myelitis anterior, or, as it is more commonly called, "infantile paralysis," is more especially liable to be confounded with hysteria, as the symptoms and progress of the case are very similar in both. The paralysis resulting from this serious organic disease of the cord attacks the adult, both in its acute and chronic forms, much more frequently than is generally believed. It is obvious that to make a clear distinction between these two disorders is of the highest importance, as the treatment suitable for the benefit of the one would be useless, or even injurious, if applied to the other. A consideration of this question appears at the present time to be worthy of discussion, as recently there has been a revival of certain energetic measures in the treatment of paralysis of a supposed functional and emotional origin; and Drs. Weir Mitchell, Playfair, and others have recorded successful cases of great interest and importance. Although it is admitted that certain procedures were followed by the most satisfactory results when employed by competent physicians, in properly selected cases, it must equally be granted that the same treatment would in different instances be followed by the most disastrous effects. The writer has not infrequently seen young women condemned to a couch for years, supposed to be suffering from spinal or uterine affection, which a little energy and determination on the part of the physician would have cured in a few weeks. On the other hand, not less often has he met with unfortunates who were scoffed at and otherwise ill-treated as being nervous and

hysterical, or imagined to be exaggerating or feigning disease, when in reality they were suffering from an organic lesion of the nervous system. This confusion has arisen from the extreme difficulty in many cases of accurately diagnosing between paralyzes, arising on the one hand from organic degeneration of nervous structure, and on the other as the result of emotional or so-called hysterical causes. It is assumed in text-books and by the profession generally that the differentiation between these is easily defined, but as a matter of fact even when the greatest care is taken this is not always the case, and after the fullest investigation much doubt remains.

With the view of illustrating this position let us take a case which not infrequently occurs in practice. A young woman suddenly or gradually becomes paralyzed in the lower extremities. This may, in a few days, weeks, or months, in different cases, become complete or remain partial. There is no loss of sensation, no muscular rigidity, no cerebral disturbances, or any affection of the bladder or rectum. The patient's general health may be robust, or it may be delicate. She may be of emotional and hysterical temperament, or, on the contrary, of a calm and well-balanced disposition. At first there is no muscular wasting, but as the disease becomes chronic the limbs may, or may not, diminish in size. The entire extremity may be affected, or only certain groups of muscles. Finally the disease may partially or entirely recover, or may remain almost unchanged for years. With such a clinical picture before us we have to ask, What is the diagnosis of such a paralysis? The description applies with equal fidelity to either hysteria or polio-myelitis, and by depending on symptoms alone it is in such doubtful cases that the decision of the question seems to depend on the accidental fancy of the medical attendant, and which so frequently results in an erroneous view being taken of the case. It is granted that the problem is a difficult one, and even a careful analysis of the symptoms does not appear greatly to assist its solution. The patient when attacked with the paralysis may be in perfect health, or the reverse; she may, or may not, be hysterical; there may be some assignable cause, or not. In all these circumstances the loss of motion may be either due to polio-myelitis or hysteria, as the former occurs with equal frequency in the robust and in the delicate, and the latter as often appears in apparently the most healthy persons as in the most nervous; the first is as likely to be present in hysterical subjects as in the reverse, and the second may follow a cold, injury, or other supposed origin of organic disease. In short, although it is true that hysterical paralysis frequently occurs in persons evidencing other nervous or emotional symptoms, these are by no means necessary to establish the diagnosis, as some of the most intractable forms of this affection have occurred in women of apparently phlegmatic temperament and well-balanced minds. Again, polio-myelitis is as likely to attack the hysterical subject as any other, and thus further complicate the inquiry. The paralysis appearing suddenly, or very gradually, applies equally to polio-myelitis or hysteria. As in the acute form of the first, the loss of motion may ensue in a few hours, and in its chronic form it may proceed very slowly and insidiously. In both the process may be partial or complete. It may attack one or more limbs, or only part of an extremity; indeed, special muscles, or irregular groups of these alone, may be affected. All these particulars equally apply to both forms of paralysis under consideration. In each the sensibility may be intact, the intelligence and special senses unimpaired, and the functions of the rec-

tum, bladder, and other organs of the body healthy. If muscular atrophy existed to a marked extent at an early period of the disease we might exclude hysteria, but in many instances in this respect there is nothing definite to be observed. The limbs in both forms of paralysis may for a long time appear of natural size. Muscular wasting, if it exists, may be obscured by an increased deposit of fat, and the hypertrophy of other structures. Again, if paralysis has existed for any length of time, the limbs may become smaller, not necessarily due to degenerative atrophy, but to simple emaciation from functional disease. Thus, as in paralysis resulting from both hysteria and polio-myelitis, the symptoms and general progress of the disease are in many cases identical, it becomes a serious practical difficulty to definitely determine whether in a given case answering to the description already detailed, it is due to degeneration of the anterior cornua of the cord, or to that less formidable affection, hysteria.

To solve the problem, as in other branches of medicine, we must not depend on symptoms alone, but, as far as possible, should bring physical phenomena to our aid for the accurate determination, demonstration, and measurement of facts. Exactly in proportion as we thus supplement our senses, so do our powers of precise research and investigation succeed. Although important advances have been made in other fields of medicine by the utilization of optics, acoustics, and other practical sciences, as evidenced by the employment of the ophthalmoscope, speculum, stethoscope, thermometer, etc., in diseases of the nervous system such methods of exact inquiry have hitherto been conspicuous by their absence. In recent times, as this want has been appreciated, endeavors have been made to supply the demand. The most successful of these is the employment of electricity as a diagnostic agent; and although our knowledge of its properties is not as yet fully developed, we have even now at our disposal such information on the subject as proves of invaluable service in the differentiation of many nervous disorders. It has already been pointed out that by symptoms alone we are not able, in many cases, to distinguish between paralysis resulting from organic disease of the anterior cornua of the cord and that due to hysteria. When we turn to physical signs, we find that there are at least two which give us definite information on the subject. These are—(1) the reflex actions following cutaneous irritation or percussion of tendons, and (2) the effects of electrical stimulation.

1. *The Reflex Actions.*—When polio-myelitis involves any reflex arc, the reflex motions associated with the track interfered with are destroyed. In the case, therefore, of paralysis of the lower limbs, resulting from this disease, all the cutaneous and tendon reflexes are absent. In hysterical paralysis, on the other hand, these phenomena are not abolished. They are usually normal, and not seldom are actually exaggerated in degree, so that not only are those which naturally exist much increased in intensity, but new reflexes not found in health are developed. Here, then, is a marked distinction between hysteria and polio-myelitis. Although this rule applies generally, it must be admitted that it is not without exception. Reflex acts vary somewhat even in healthy persons, and in rare instances have not been obtainable. Again, it is just possible that in degeneration of the anterior cornua certain parts of their substance might be preserved, and although paralysis existed, certain reflexes might be elicited. In hysteria also the reflexes are sometimes absent for reasons not easily explained. Such cases, however, are extremely rare, and the general law holds good that in par-

alysis from polio-myelitis the reflexes are impaired or abolished, while in that from hysteria they are normal or increased.

2. *The Electrical Reactions.*—These are for the most part definite and conclusive. In acute polio-myelitis the excitability of the affected nerves is very rapidly lost, so that in from a week to ten days after the onset of the paralysis the response is altogether abolished to the electric stimulus. Very soon afterwards the muscles are affected, and then ensues all the characteristic quantitative and qualitative changes met with in neuro-muscular affections. In the chronic forms of the disease the same takes place, but in a more gradual and progressive manner. In hysterical paralysis, on the other hand, the electrical reactions remain practically normal. In some cases there may be quantitative increase of response, indicating hyper-excitability of the nervous system, but these changes are slight in degree, and there are never qualitative alterations. In very chronic cases also, in which the patient has been bedridden for years, there may be quantitative diminution of response due to prolonged disuse of the muscles, or to increased resistance to the current from an augmented deposition of subcutaneous fat as the result of want of exercise. In such cases the loss is never complete, and the change is one of degree only, and not of character.

Thus in electricity we have an agent which enables us in the large majority of cases to detect with accuracy and certainty between polio-myelitis and hysteria, and so far as my own experience has gone, I have never met with a case of the former which did not present some characteristic abnormal reactions, nor an instance of the latter in which these were developed.

It is to be observed that great care and much dexterity and experience are necessary for profitable electrical investigation. It cannot be exactly asserted that an expert alone is necessary for this purpose, but certainly it cannot be satisfactorily conducted except by those who, through knowledge and practice, have overcome the technical and manipulative details necessary for its successful performance. The system of wildly dabbing sponge electrodes on the skin without a definite method, is absolutely useless as a means of deducing trustworthy diagnostic data, and it is the popular use in this way which has hitherto been so fruitless and brought a valuable physical agent into discredit. A novice, ignorant of the use of the stethoscope, would hear little or nothing on applying it to the chest, and still less would he deduce those important conclusions which the experienced physician would recognize. Precisely in the same way is electricity a means towards an end, which can only be put in successful operation by a practical knowledge of the agent employed, with dexterity and experience in its administration.

It would be out of place here to describe either the method of procedure or the particulars of the reactions found in the two forms of paralysis under discussion. These have elsewhere been considered in full detail.

The general conclusions to be drawn from the foregoing remarks are:—(1) That, judging from the history, symptoms, and progress of the case, in a large number of instances it is difficult or impossible to diagnose between paralysis from hysteria or from polio-myelitis; (2) that a correct differentiation between them is of the highest importance, as the treatment successful in the one is useless or may be injurious in the other; (3) that in order to arrive at a true diagnosis, we must as far as possible apply physical agents in their investigation; (4) that in the diseases under consideration

the conditions of the reflexes, resulting from physical manipulations, afford us valuable information, although open to certain exceptions; and (5) that electricity supplies us with an agent which, in the large majority of cases, will definitely enable us to correctly decide whether a given paralysis is due to organic disease of the anterior cornua of the cord, or to that affection to which we apply the term hysteria.

ON BONE-SETTING (SO-CALLED).¹

By R. DACRE FOX, F.R.C.S. Edin.,

Surgeon to the Manchester Southern Hospital, Surgeon to the Manchester Police Force, Chief Medical Officer to the Manchester, Sheffield, and Lincoln Railway, etc.

THIS is the first time in the history of the British Medical Association that so-called bone-setting has been seriously discussed, and I think it is matter for congratulation that we have at last set ourselves impartially to examine the practice, notwithstanding that it is almost exclusively employed by a class of persons who are without our pale. The literature of bone-setting is scanty. Dr. Wharton Hood's handbook, giving an account of the late Mr. Hutton's method of setting free stiff limbs, is, so far as I know, the only attempt at a systematic exposition. There are, in addition, some papers scattered through the various journals, by Mr. Adams, Mr. Howard Marsh, and others, stating their opinion as to what cases are most likely to be benefited by the forcible bending of joints, and giving instances of ill results that have followed such treatment in unsuitable cases. For nearly three years I was assistant to the late Mr. James Taylor, M.R.C.S., of Whitworth in Lancashire, the last direct descendant of a family that had practiced bone-setting in that village for more than two hundred years, and I think I may perhaps be able to throw some light on the subject of this discussion.

Much misconception exists as to the practice of bone-setters; many of the methods of treatment popularly attributed to them have no other existence than in the imagination of ignorant patients, whose stories we as a profession are perhaps rather too ready to believe. It is certain that some families—notably the Taylors, Huttons, and Masons—have by their manipulative and mechanical skill justly acquired a great reputation. In what has their practice consisted? First, in the treatment of fractures, recent dislocations and sprains; secondly, in the cure of stiff joints, re-setting of fractures, and correction of deformities. The general impression appears to be that the bone-setter's art consists of nothing more nor less than the forcible and reckless "cracking up" of stiff joints so as to make the lame man walk as if by a miracle. The practice at Whitworth was a large one, furnishing constant employment for at least two active men, and consisting chiefly of the cases I have mentioned. Speaking from memory I do not believe that fifty points of all sorts were "cracked up" during the time I was there; but it was not an uncommon event to have to put up half a dozen fresh fractures and twice as many recent sprains in a single morning. In the North of England the origin of nearly all the men who are fairly good at bone-setting can be traced to the Whitworth surgery, and while, so far as I know, the Taylors in their various settlements at Whitworth, Todmorden, Lockwood, and Oldfield

¹ Abridged from a paper read at a discussion before the Surgical Section of the annual meeting of the British Medical Association at Worcester, 1882.

Lane were the only qualified surgeons who practiced bone-setting; amongst the hills and dales of Lancashire, Yorkshire, and the Lake district, there were many who did so without being qualified, some of whom, I must in all fairness say, put up fractures uncommonly well. But apart from the legitimate credit they have won by the skill displayed in their handicraft, they owe some of their success to the carelessness or indifference of the general body of practitioners, who are apt to overlook little injuries which often become very painful and troublesome. It sometimes seems to me that it is beneath the dignity of the ordinary practitioner to employ any active treatment whatever for a sprain. It is hardly fair then to gauge the work of bone-setters solely by their method of treating diseased joints (probably the most unsatisfactory class of cases in the whole realm of surgery), but we ought also to take into account the patience and skill they display in the treatment of injuries for which they are not unfrequently consulted by the patients of qualified practitioners. I have no desire to hold a brief for every idle fellow who calls himself a bone-setter, but I am anxious to give credit where credit is due, and to explain that the art of bone-setting is not what it is often thought to be, a mere mixture of charlatanism and good luck.

I purpose chiefly to consider that class of cases to which Mr. Adams and Mr. Marsh have more particularly referred. Dr. Hood (*loc. cit.*) has made out a somewhat extensive list of causes for stiff or weak joints, but I think he had in his mind rather what was *likely* to come to the bone-setter than what actually did come. From my own experience I should classify weak joints as follows:—

1. Those that have become stiff from enforced rest.
2. Those that have become stiff from chronic disease.
3. Joints stiff from injury to the bones entering into their formation.
4. Joints stiff and weak from sprains, including displacement of tendons and partial luxation.

Apart from the previous history of the case, and the evident existence of constitutional disease, there are some external appearances which help to distinguish cases and to afford indications for treatment, and of these the bone-setters have learned by experience to avail themselves.

1. In the first class I have mentioned, the stiffness of the structures about the joint impeding its movements is the result of purely mechanical causes, is in fact simply due to prolonged disuse. No cause for functional activity exists, and consequently the elasticity, the flexibility, and power of adaptation to movement in the parts about the joints not being required, they become stiff and rigid. No degenerative changes, however, take place, and they are capable of being recalled into activity unimpaired. In such a joint the bony points and the outlines of the tendons and ligaments about it, seem unnaturally prominent, probably from absorption of the adipose and connective tissue; the rigid ligaments impart a sense of hardness, and if the limb be flexed to its utmost it shows considerable resiliency. Such joints may, I believe, be "cracked up" without fear of consequences, and this constitutes one of the successful operations of bone-setters. My own recollection carries me back to some apparently almost miraculous results. I am convinced that *suddenness* ought to be insisted upon in doing this; the advantages derived from it being, I believe, mainly due to the fact that it is less likely to set up any irritation in the joint than the "dragging" of gradual extension.

2. In the next class of cases, in which stiffness

is due to degenerative changes, the external appearances are exactly reversed, the outlines of the joint are more or less gone. In these cases, no matter the character of the disease, manipulative interference is positively vicious; and while it is in them that ignorant bone-setters do so much mischief, the better informed, by the use of splints and well-applied pressure, are highly successful in their treatment.² I am sorry to say very many cases of this kind come to bone-setters which have not been properly treated before, owing to their not having been recognized, especially hip-joint disease.

3. In the third class of cases, in which a fracture has taken place into the joint, causing stiffness, the condition is due to disturbed relationship of the bones from faulty setting, and is recognized by comparison with the bony landmarks of the sound limb. In these cases forcible treatment does good, though of course the result is in proportion to the amount of bone-displacement, but it should be supplemented by passive movements for some time. In joints stiff after diagonal fracture through the condyles of the humerus, so common in children, I have seen many most gratifying results; one in a boy about twelve years old, whose elbow had been stiff three years, is especially impressed upon my mind.

4. In the fourth class of cases, and those to which I would draw particular attention; I include lameness and weakness, the result of the various forms of injury, which we group together under the general term "a sprain." I affirm most unhesitatingly, from an experience of some hundreds of cases, that nothing has done more to lower the prestige of regular practitioners, and to play into the hands of unqualified bone-setters, than the way in which so many practitioners tamper with a sprained joint. Sprains, of course, vary greatly in severity; they may be broadly divided into two kinds, of which one consists merely of a temporary over-distension of the parts around a joint, which rest and anodyne applications soon cure, while the other involves pathological results of a much more serious nature. A severe sprain is the sum of the injuries that the parts in and about a joint sustain, when, by their passive efforts, they exercise their maximum power of restraint to prevent luxation. Under such conditions I conceive the following changes to take place in the integrity of a joint. In the case of the synovial membrane, temporary hyperæmia accompanied by pain, and some slight effusion into the cavity of the joint. In the case of the tendons, overstretching and loosening of the lining membrane of their sheaths, more or less disturbance to the adjacent cellular tissue forming the bed of the tendon groove, and hyperæmia with exudation of plastic fluid, subsequently forming adventitious products. In the case of the non-elastic fibrous ligaments—firmly attached at either end to the adjacent periosteum—overstretching, mostly involving partial rupture, with swelling, softening, and disintegration of their structure. It is beyond the purpose of this communication to draw attention to the plan of treatment adopted by bone-setters under these circumstances: it is, however, described in a paper of mine, of which an abstract is given in the *British Medical Journal* of Sept. 25th, 1880. The stiffness of a sprained joint is *partial*. The surface is generally cold, and more or less oedematous, and each joint has one particular spot in which pressure causes acute pain; the bone-setters have learned by experience the situation of these spots, and this fact has done more than anything to strengthen the popular faith in their intuitive skill; they certainly form an important guide

² Rheumatic cases sometimes do well for a time, but invariably relapse.

to treatment, since they indicate the seat of greatest injury to the ligaments and point out where their power of passive resistance has been most severely tested, and where adhesions are most likely to have formed. Dr. Hood, in his record of Mr. Hutton's practice, has enumerated some of these painful spots; the chief of them are as follows:—

1. Over the head of the femur in the centre of the groin, corresponding to the ilio-femoral band of the capsular ligament (which is most severely stretched when the thigh is over-extended, as when the trunk is flung violently backwards, the commonest cause of a sprained hip).

2. For the knee-joint, at the back of the lower edge of the internal condyle—in other words, at the posterior border of the internal lateral ligament, where it blends with Winslow's ligament, and where the semi-membranosus tendon is in intimate relation with it. These parts suffer most because, as Mr. Morris says, "During extension they resist rotation outwards of the tibia upon a vertical axis," and a sprained knee is almost always caused by a twist outwards of the foot.

3. For the shoulder at the point corresponding to the bicipital groove, because in nine cases out of ten a man sprains his shoulder to prevent himself from falling, his hand grasps the nearest support, the body is violently abducted from the arm, the long head of the biceps is called upon to exert its utmost restraining power, the bicipital fascia is over-stretched and the tendon very often displaced.

Again, for the elbow the painful place is at the front of the tip of the internal condyle; the fan-shaped internal lateral ligament has its apex at that point, and it is most stretched in over-supination, with extreme extension of the forearm. On the front of the external malleolus, at the apex of the plantar arch, the tip of the fifth metatarsal bone, the styloid process of the ulna, the inside of the thumb, and the annular ligament in the front of the wrist, are respectively the most painful spots when those joints are severally sprained.

The manipulative part of the treatment of joints stiff from being sprained may be briefly said to consist in pressure over the part most injured, and momentary extension of the limb, followed by sudden forcible flexion. The method of doing it varies with each joint, and I can with confidence refer you to the descriptions given by Dr. Wharton Hood, as being faithful word-pictures, supplemented, too, by very accurate drawings.

The following are some of the lesser injuries the non-recognition of which has frequently come under my notice at Whitworth. In the upper limb: Fracture of the tip of the acromion; partial luxation of the acromio-clavicular and sterno-clavicular joints (often happening to men who carry weights on their shoulders); partial dislocation of the long head of the biceps, with over-extension of the bicipital fascia (common in men who throw weights or use a shovel, as malsters or navvies). Dislocation of the head of the radius forward on the condyle, which is very common in children, and has a marked tendency to cause stiff elbows; fracture of the tip of the internal condyle; overlooked Colles' fracture; partial luxation of the head of the ulna (impeding supination of the hand, and having a tendency to gradually grow worse); severe sprain at the carpo-metacarpal joint of the thumb (very common in stonemasons, and caused by the "jar" of heavy chisels).

In the lower limb: Fracture of the fibula just above the malleolus and at its tip (these are fruitful sources of lameness, often overlooked, and, if of old standing, very troublesome to treat); partial rupture of the ligamentum patellæ at its insertion into the tubercle of the tibia, which is much more

common than is ordinarily supposed;³ neglected over-stretching of the ligaments of the plantar arch, and tearing of the plantar ligament at its insertion into the os calcis; rupture of the penniform muscular attachments of the tendo Achillis, and muscular hernia in the calf.

I trust I shall be forgiven if I have dwelt too much on the *étouderie* of some of us, but I am sure so-called trifling injuries deserve more attention at our hands, since living at the high pressure men do nowadays, with every part of their bodies tested to its utmost capacity, the slightest impairment of the mechanism of a limb must be an incalculable source of personal annoyance, discomfort, or disability.

CONGENITAL CYSTIC HYGROMA.¹

By EDMUND OWEN, F.R.C.S.

Surgeon to St Mary's Hospital.

In the volume of the Transactions of the Medical and Chirurgical Society for the year 1839 is a paper by Mr. Caesar Hawkins upon the subject of the present communication. It is, so far as I know, the first treatise that we have upon these cystic growths, and I very much doubt if any matter of importance, either as regards their pathology, diagnosis, or treatment, was left by Mr. Hawkins for future writers to fill in.

Congenital cystic hygroma is by no means of unfrequent occurrence, and it is strange that so little notice is taken of it in our works on general surgery.

The first case to which I will direct attention is that of the little girl that has just been examined by the meeting. She is now between three and four years old. A few days after birth her mother noticed a swelling under the right side of the tongue, which, on being shown to the doctor who attended her, was called a "ranula." He refused, however, to interfere with it. The suppurated ranula grew, extending across the floor of the mouth and amongst the muscles behind the symphysis of the maxilla, until a definite tumour appeared against the angle of the jaw. The little patient was then brought to me, when I told the mother that nothing was to be done to the tumour, which, as it was growing rapidly, might entail serious consequences. My impression is that this enormous mass has now ceased to grow. It is certainly harder than it was, though its cystic nature is still quite evident. It is not tender, nor does it apparently interfere with the child's health or with the nutrition of the skin. I am still content to watch and wait.

The second case is that of a boy of five months who was under my care at the Children's Hospital. He had a cystic hygroma of the size of a walnut in each subclavian region and in each axilla; it was doubtful whether the upper and lower tumours were in communication. Mr. Thomas Smith saw the child with me, and we agreed that no active treatment should be undertaken. When I next saw the little patient, after an interval of three weeks (the mother lived at a distance, and was not led to expect much from treatment), the upper pairs of tumours had almost met across the episternal region; there was difficulty on swallowing, and commencing oedema of the eyelids and of each upper extremity. Translucency showed the cystic nature of the superficial part of the subclavian masses. A week afterwards the mother came to

³ I have seen almost complete rupture unrecognized; while tearing of the ligament from its extensive insertion into the surface of the tibia is very frequent.

¹ Read before the Medical Society of London, Nov. 6th, 1882.

tell me that the child had died on the previous day, and that the tumours had gone on growing so that at last the child could hardly breathe. She said also that the oedema of the hands and arms had gone on increasing until the day before the death, and that the legs and thighs had towards the last days also begun to swell. Her opinion was that death was caused by suffocation. No post-mortem examination was made.

Here, then, are reports of two cases of, so far as one can tell, a similar pathological nature, in one of which fatal complications brought on a sudden termination, whilst in the other a quiescence which one hopes is genuine seems to point to the fact that activity of growth has given place to spontaneous degeneration or atrophy. It is impossible to say what course a cystic hygroma may take; whether it is about to undergo immediate or future growth, or whether it is about to undergo interstitial changes which shall reduce it to a "loose pendulous bag of fat." Inflammation of the tissues, either spontaneous or induced, will at times determine their atrophy, and from the increasing hardness in the case of the little girl, I suspect that such a change is at hand. As Mr. Hawkins remarked, some of these tumours look as if they could be easily dissected out, but to remove one from the neck the operator may have to work around the carotid vessels and possibly behind the pharynx. I once dissected such a tumour from the side of the chest, and even then I had to root it out from beneath the border of the latissimus dorsi. Mr. Hawkins suggested that their treatment should consist in puncture of the larger cysts, and in the application of pressure and counter-irritants. To which one might perhaps add that in certain cases atrophy may follow the inflammation caused by the presence of one or more setons through the mass. Probably spontaneous inflammation is their most desirable complication.

In conclusion, I would remark that, as in the first case, a congenital cystic hygroma in the sublingual region may be mistaken for a ranula, an error in diagnosis which is more likely to lead to disappointment than to damage. That in whatever situation it may occur it is apt to be mistaken for a subcutaneous naevus, or for one beneath the mucous membrane; and, lastly, that at times the resemblance to a fatty tumour is extremely close.

A second child exhibited possesses the remains of a hygroma on the arm. The patient has been three years under observation, but the mass, which now resembles a diffuse fatty tumour, was, when first under observation, of evident cystic formation. This is the only instance which I have seen of a congenital cystic hygroma situated upon an extremity; their favorite seat is the armpit and the floor of the mouth.

Seymour-street, W.

PENETRATING WOUND OF THE ORBIT, INVOLVING THE BRAIN; NO MARKED SYMPTOMS UNTIL THE THIRD DAY.

By ENOCH DUE PRIDEAUX, L.R.C.P., M.R.C.S., etc.

W. T—, aged twelve, was playing with two other boys on the morning of Feb. 24th. The boys had hazel sticks about two feet long and half an inch in diameter, pointed at one end and cleft at the other, and in the cleft they fixed stones. One boy in alighting the stone let the stick slip, which went off with the stone and struck the patient in the right eye, entering by the pointed end. The boy pulled the stick out and walked home, about a mile, and told his father he had been

struck in the eye. His mother bathed the eye, which appeared uninjured, and thought no more about it. They remarked that blood came from his nose and mouth. However, the boy remained well until the following Saturday. When he got up that morning his eyelids were so swollen he could not open them, he complained a good deal of pain. His eye was poulticed, but he was not kept in bed. He took his meals; and beyond complaining of the pain was not otherwise affected. In the evening, after he had taken his tea and gone to bed, he was found insensible, and I was sent for. When I arrived the boy was quite unconscious and very restless, turning over and over. Pulse 120, regular; temperature 101°. The eyelids were so much swollen I could not open them. A little pus was oozing out at the inner angle of the eye and some coming down the nostrils. He was quite unable to swallow. I placed a little calomel upon his tongue. The next morning he was quieter; his attention could be arrested by shouting to him. I got him to swallow a few spoonfuls of milk. Pulse and temperature the same. He died the same night, becoming more and more comatose during the day.

I made a post-mortem examination, and found a small external penetrating wound at the inner angle of the eye, but all the structures of the eyeball were quite uninjured. Internally I found a small ragged hole, large enough to admit the little finger, at the junction of the sphenoid and ethmoid bones. The under surface of the anterior lobe of the right cerebrum was completely destroyed. On placing the brain in water it all washed away, leaving a large ragged cavity the size of a duck's egg, and in which were two pieces of bone each as large as a threepenny piece. The whole brain was highly congested, with a patch of fresh lymph as large as a shilling under the dura mater at the vertex.

Wellington, Somerset.

NOTE ON THE USE OF BOROGLYCERIDE IN THE TREATMENT OF WOUNDS.

By HENRY A. LEDIARD, F.R.C.S. Eng. and M.D. Ed.,

Surgeon to the Cumberland Infirmary.

ON March 19th of this year I was some distance from home, consulting with Dr. Walker, of Stapleton, in this county, and he mentioned to me that a new antiseptic (boroglyceride) was creating some stir in Germany, and offered to provide me with some if I would use it and record my experience. Accordingly a few weeks ago I received four ounces, which were dissolved in water and used in the strength of 1 to 20 and 1 to 40. In appearance boroglyceride is like large cakes of isinglass, of the color of gum acacia, sticky as toffee, and has a slightly warm taste of indefinite and transient character. In solution it is colorless and almost tasteless.

We are now in possession of a few facts in reference to the use of this new antiseptic as applied to wounds, many of which have been treated with it, but owing to the supply from Dr. Walker having scarcely kept pace with the demand, the trial has not been as complete as could have been desired. A case of Syme's amputation for ankle-joint disease was treated with boroglyceride from the first—i. e., the flaps were washed with the solution, and the stump wrapped in lint steeped in 1 to 40 solution; the subsequent dressing consisted in washing out the cavity and using lint as before, the result being as excellent as, but not more excellent than, I have seen in similar cases treated with dry lint. The

stump kept sweet to the nose, but the drainage-tube and pus squeezed from the stump were not so. It is probable that we used the solution too sparingly; and allowance must be made for this, for occasionally we had to wait for the arrival of a fresh supply. Another case of railway smash of the foot (Syme's amputation also) which was not healing kindly (Listerism having been relinquished on account of putrefaction), was treated with boroglyceride, and although healing was neither interfered with nor accelerated, yet smell was unquestionably kept down. Several wounds, the result of either accident or surgical operation, have also been treated with boroglyceride with satisfactory results, and the conclusions I have arrived at so far are as follows: For open wounds or wounds with open cavities boroglyceride in solution will be found to be a non-irritating and powerful antiseptic, in no way interfering with natural healing processes, and in no degree troubling the skin around a wound; but where shut cavities exist, as in stumps after amputation, although syringing with the solution be adopted, yet the discharge collecting within is not kept sweet. I feel sure that much remains to be done to develop the use of this new antiseptic, which, on account of its non-irritating properties, will prove of much value in the treatment of wounds. To claim for any antiseptic a value beyond one's experience would be to court distrust, and I prefer to speak hopefully rather than positively.

Mr. Barwell's paper in *THE LANCET* recently certainly supports our experience of the value of boroglyceride, but we have not succeeded in preventing rises of temperature, any more than we have succeeded in obtaining union without one drop of pus, neither have we seen remarkable results as to healing by first intention; in fact, the results may seem to be *nil*. I think the use of stronger solution than 1 to 40 or 1 to 20 may be tried, and the lint around the wound should be kept constantly moistened with the solution. As far as I am aware boroglyceride is innocuous, a matter of great moment, when one recollects how many patients have been poisoned by doses of carbolic acid by inadvertence, how many untoward symptoms have been put down to the use of the carbolic spray and absorption of carbolic acid.

I hope on a future occasion to add more to this brief note, which must conclude with an acknowledgement of thanks to Dr. Walker, who manufactured the boroglyceride himself.

Carlisle.

THE INTRA-VENOUS INJECTION OF FLUID FOR SEVERE HÆMORRHAGE.

By C. EGERTON JENNINGS, L.R.C.P. Lond.,

Resident Accoucheur, and Formerly House-Physician, at the London Hospital.

(Concluded from p. 367, Nov., 1882.)

STUDENTS, with smiling faces, are rapidly leaving the theatre of one of our metropolitan hospitals. The most brilliant operator of the day has just performed immediate transfusion with the greatest success. By means of a very beautiful instrument, the most complex and ingenious that modern science has as yet produced, a skilful surgeon has transfused half a pint or perhaps a pint of blood from a healthy individual to a fellow-creature profoundly collapsed from the effects of severe hæmorrhage. Some little difficulty was experienced prior to the operation, as one of the many stop-cocks of the transfusion-apparatus was found to work stiffly, but this error was quickly rectified by

a mechanic in attendance. Towards the close of the operation the blood-donor, a powerful and heavy young man, swooned. Two porters carried him on a stretcher into an adjoining room, his wounded arm being bandaged up, *secundum artem*, by energetic dressers. Diffusible stimuli were exhibited by the mouth, nostrils, rectum, and skin. The man rallied in due course, being well cared for by a group of students and nurses deputed to look after him. The wound in his arm will probably heal speedily, or a few weeks later he may possibly apply at the out-patient department of the hospital, presenting an ugly-looking pulsatile tumour, associated with a thrill and rasping bruit, connected with the vessels in the cubital triangle—a most unfortunate accident having clearly happened here, of which a record promptly appears in the columns of *THE LANCET*.

Time rolls on, and a spectator of the duplex operation, possessed of an instrument such as he had seen employed, finds himself at midnight, in a lone house in the country, face to face with an alarming case of post-partum hæmorrhage. He has adopted the modes of treatment recognized as judicious for the condition before him. He has employed active hæmostatic agents, and finally that potent but highly dangerous syptic, perchloride of iron. His patient is blanched and collapsed to the last degree. Are not her blood-vessels so thoroughly drained of blood that there is not sufficient of that element circulating in the uterine walls to stimulate to *permanent* contraction its muscle fibres? Is not this the very case for transfusion? The accoucheur puts his apparatus in order (he may not have it with him, and be obliged to send home for it) and selects a blood-donor. He has little time or opportunity under the circumstances I have depicted to find an adolescent, healthy beyond a doubt; little time has he to eliminate the existence of syphilis or of other specific communicable diseases by a well-planned examination of the youth, nor to obtain a knowledge of his previous history and mode of life. The operation is commenced; the blood-donor faints; the friends of the patient, the necessarily improvised assistants to the accoucheur, faint also. The operation is abandoned, and it and he who proposed it fall into disrepute. But there may fortunately have been time to summon a skilled assistant. The veins both of blood giver and recipient may have been dexterously opened, and transfusion commenced. Still, accidents may even now happen; a small coagulum may form within the apparatus, or a little air gain access through some contingency to the veins operated on.

The picture is carried far enough. Is the operation of immediate transfusion, as taught and elaborately performed in hospital practice, where there is every means of ensuring success, one of universal application? Is it one that can always be performed when most needed—under urgent circumstances and at a moment's notice, often in the night, at Land's End, John O'Groats's house, or Ratcliffe-highway, and by an unaided operator, with everything against him?

If the practitioner have not at his command, when circumstances indicate its employment, a transfusion apparatus, what can he do? Imitating Treves, he may file down the bone nozzle of an aural syringe, and through this rude but efficient cannula administer an intra-venous injection.¹ No satisfaction can possibly be greater than, under compulsion, to have operated successfully in such a manner. But would it not be far better were some simple method known, which, being of

¹ *THE LANCET*, 1877.

ready application, and not requiring complex, expensive instruments, difficult to manipulate and otherwise objectionable, might be employed by every medical man in the kingdom with ease, expedition, and safety? This question forced itself upon me very strongly when, in the case I have recorded,¹ I administered, with the three-ounce metal transfusion-syringe of the London Hospital (as represented by Fig. 1), an intra-venous injection, the procedure being, in my estimation,

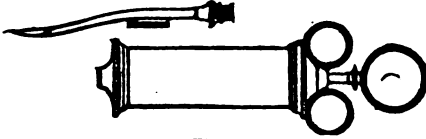

Fig. 1.

fraught with the risk not merely of admitting air while detaching the body of the syringe from its nozzle by means of a screw, for the purpose of refilling the instrument, but also with the danger of injuring important structures adjacent to the vein selected for operation (in the case of the median basilic vein, the brachial artery) with the point of the nozzle; for the syringe being many times heavier than the nozzle it was impossible for me to hold the latter steadily during the proceeding. Fig. 2 illustrates an instrument which, to obviate the objections I have mentioned, has been made for me by Maw & Co., and has been briefly described in my preceding paper. It is essentially a syphon, consisting of five feet of elastic tubing, one extremity culminating in a vulcanite bell-shaped opening guarded by a metallic grating, the other joining a silver stopcock, to which a cannula can be attached. A short distance from this extremity the continuity of the syphon is interrupted by a small glass tube, inserted for purposes of observation; a few inches higher still is an exhausting bulb, by which the air present in the instrument can be expelled prior to use. A semicircular canal of vulcanite protects the rubber tube where it passes over the edge of the vessel containing the solution for injection. The cannula is serpentine in form—following in this respect Treves's pattern,

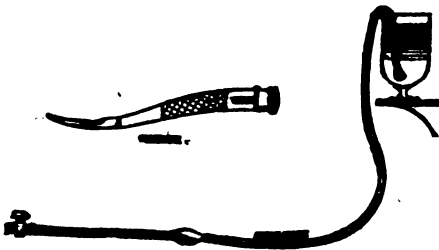

Fig. 2.

compressed a little laterally and embossed at the part where it should be grasped by the operator's fingers. It gradually tapers to a blunt extremity, at a distance of half an inch from which is an oval aperture for the transit of the vivifying fluid. This aperture can be closed by the pulp of the index finger whilst the point of the cannula is being inserted into the vein; as the finger is withdrawn the cannula is simultaneously pushed onwards; the possibility of the entrance of air into the vein, if this method be adopted with ordinary care, being certainly avoided. The cannula is grooved fifteen-

sixteenths of an inch from its point, by which means it can be secured with a ligature and maintained *in situ* when fairly within the vein. Always mindful of the fact that it must become the duty

Fig. 3.

of every surgeon at some time or other to perform transfusion, like tracheotomy, entirely unassisted, or his patient must succumb. Fig. 3 represents an automatic retractor, which, being capable of almost instantaneous application, might often be very serviceable.

In conclusion, I beg leave to acknowledge many valuable suggestions I have received in reference to this syphon from Dr. Palfrey and Mr. Fenton-Jones, and to express the hope that by the substitution of simple for complicated methods of transfusion or intra-venous injection, every instrument devised for its performance being safer and surer in its mode of action than those which have preceded it, the operation will at length be elevated from the dazzling but delusive position it at present occupies to one of true utility to mankind.

CASE OF CARIES OF THE ATLAS AND AXIS.

By JOHN DEARDEN, M.D., F.R.C.S.E.

THE following case appears to present some features of interest, which I have thought worthy to place before the readers of THE LANCET.

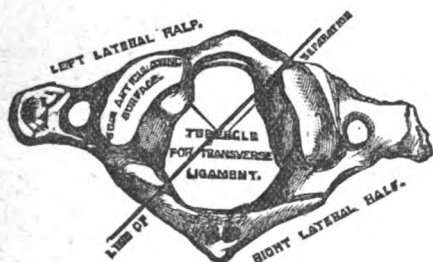

On Dec. 26th, 1881, I was called to attend B. H—, aged forty-two. He is of medium height, tolerably well-developed, pulse and temperature normal, lungs and digestive organs apparently healthy, and of temperate habits. He complained of acute, darting pains up the left side of the neck, extending to the head, taking the course of the trapezius muscle of that side; he also complained of a dull, aching pain on the top of the head, about the junction of the occipital and parietal bones. The pain in the neck was aggravated on the slightest movement of the head. There was enlargement of two of the cervical glands to about the size of a walnut, also considerable rigidity of the muscles of the neck. No difficulty was complained of either in swallowing solid or liquid food, of which he took a fair quantity. The head was drawn slightly forwards and towards the right side; the intellect was quite clear, and there was no impairment of muscular movements in any part of the body. His only complaint was the "excruciating" pain already referred to, and which rendered it difficult to raise himself from the recumbent to the sitting posture, the head having to be steadied by both hands.

The patient stated that he lived in Australia eleven years ago, and had frequently "camped" out on the open ground; also that he had a severe fall from a considerable height (fifteen feet), alighting upon his back, but "thought he got completely over the effects." He first noticed "the pain" about three and a half years ago, but had been able to attend his business, that of a grocer, up to the time of my first visit. He stated that he never had syphilis. On the date first mentioned he was not confined to bed, but was able to be up and about, taking short walks. In March, 1882, as there had been no improvement he expressed a

¹ *Ibid.*, Nov., 1882, p. 366.

wish for change of air, so he went to Blackpool. After a short stay he went to Buxton, and placed himself under hydropathic treatment. Finding himself getting weaker and the pains considerably increased, he returned home, arriving on May 23rd. From that date he was not able to sit up more than a few minutes at a time, and that at intervals of nearly a week. On June 23rd the voice became squeaky, and diminished in resonance daily until the termination. Bilious vomiting occurred at intervals; increased secretion of mucus about the fauces and pharynx, which was got rid of with some difficulty; dribbling of saliva from the right angle of the mouth; the above symptoms indicating that the pneumogastric and recurrent laryngeal nerves were implicated in the disease. On June 30th he was seized with violent muscular contraction, raising himself suddenly to the sitting posture, the legs being shot off the bed quite rigidly. He immediately expired.

By his special request the head was examined (Dr. Ruttle, of Accrington, kindly assisting). On removing the calvaria extensive adhesions were found existing between the dura and pia maters, chiefly situate at the apex; the brain appeared healthy throughout. On looking into the foramen magnum the bare and roughened surface of the top of the odontoid process was visible. An opening was then made along the posterior border of the sterno-mastoid muscle. A large collection of pus was found on the anterior surface of the spinal canal, but not opening into it, the theca spinalis being whole. The left lateral half of the atlas was

extensively necrosed and completely separated from the other portion (the dotted line in the diagram showing the separation), and could be easily removed by the fingers. The right half was represented by only small pieces of necrosed bone, both articulating facets of the occipital bone, and all those of the atlas, were also found to be necrosed; the transverse ligament of the atlas was absent.

It does not need any lengthy description or vivid portraiture to see what the effect of violent and sudden contraction of the sterno-mastoid muscles must be. The head would be drawn forwards, the transverse ligament being absent allows the odontoid process with the axis to slip backwards, crushing the medulla oblongata against the posterior part of the foramen magnum in this case, as there was little of the atlas left—ergo, instant death.

The treatment had been various, chiefly iodide of potassium at one time, quinine at another, now counter-irritation to the nape of the neck, again sedative applications. The only medicine I gave him was quinine with gelseminum and a liniment composed of equal parts of chloroform, tincture of opium, belladonna, and aconite, which he used freely, and expressed himself relieved by it, at least for a short time.

He had been seen and attended by several gentlemen, but the (apparently hidden) nature of the

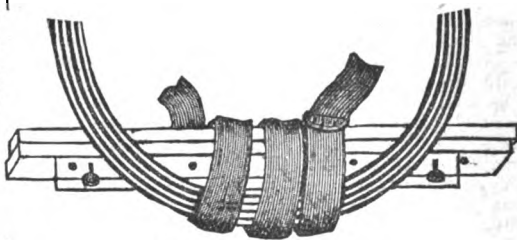

disease was, I think I am right in saying, never discovered during life. I thought the symptoms pointed either to aneurism of a basilar artery or abscess at the base of the brain.

Church, near Accrington.

A NEW CRADLE, SPECIALLY ADAPTED TO FIX EITHER TO A BACK-SPLINT OR TO THE LIMB, AS REQUIRED.

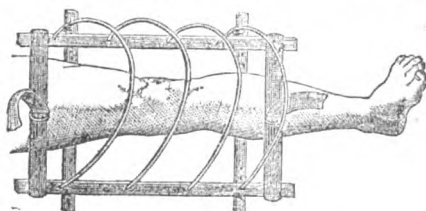

By WM. THOMAS JACKMAN, M.R.C.S., etc.

THESE small cradles will be found of great service to surgeons where it is desired to keep the bed-clothes raised from an inflamed joint, either to avoid pressure or to increase the efficacy of evaporating lotions, by allowing above the limb a space into which evaporation can take place. They can be fixed securely to a back-splint, or to the limb if no splint is being used, by means of a broad strap of webbing; the space between the limb and the

The cradle packed for carrying.

hoops of the cradle can be regulated as required. The cradles for the knee and ankle are made of wood, and consist of four movable cane hoops three inches and a half apart, capable of being fixed at any desired height over the limb into side bars of wood sixteen inches long. The cradle is further secured by means of two sliding laths

The cradle for the knee, adjusted.

which pass under the limb and are fixed by pegs; these being adjusted, assist in the regulation of the height of the hoops. The whole apparatus is very portable, light, cleanly, and of easy adjustment. The length of the cradle is such that only the inflamed joint is protected from the clothes, thus avoiding discomfort to the patient, which the large cradles resting on the bed, as at present used, necessarily cause. The cradles, being really one with the splint or limb, can be conveniently used in cases where the limb is slung. The small space the cradle takes up in the bed is a great convenience. For the elbow-joint light angular cradles of stout iron-wire are more suitable; these are fixed to the splint or limb in the same manner as the wooden cradles. Messrs. Ferguson & Co., of Smithfield, are the makers.

Coggeshall, Essex.

CASES FROM COUNTRY PRACTICE.¹

By H. MALLINS, M.B., M.Ch. T.C.D.

CASE OF TUMOUR OF THE CEREBELLUM.

ANNE L.—, aged sixty-one years, a laborer's wife, the mother of a numerous family, first came under observation on March 15th, 1881. Her family history is very good; her mother is still alive. With the exception of some gouty attacks, she has enjoyed good health until about a year ago, when she commenced to complain of headache. She was considered to be suffering from migraine, and improved somewhat under treatment directed against that affection. The pain in the head, however, did not entirely leave her, and towards the end of July it again became very severe, radiating from the occipital region forwards all over the head, attended with frequent vomiting and extreme tenderness of the scalp. Double vision was now noticed for the first time. No paralysis could be made out, but a condition of general muscular debility was well marked. From this time to the date of her death she was confined to her bed. When able to walk no tottering gait had been noticed. The diagnosis of a tumour of the cerebellum was now made, grounded chiefly on the two symptoms of persistent pain in the head and constant vomiting.

Nov. 1st: The pain is now referred more to the right frontal region than elsewhere. Since last report the sight of the left eye has been completely lost; both pupils are normal. There has been no vomiting for the last two weeks.—7th: The sickness has returned. There is slight left strabismus. The sight of the right eye is becoming affected. The conjunctivæ of both eyes are injected, and are the seat of much "pricking and watering."—14th: The pain, which is as severe as ever, is now described as being of a pulsatile character, and is felt all over the head. The sight of the right eye is a little improved. A feeling of numbness is felt over the whole body when she assumes the standing position, which she cannot do without assistance. The vomiting continues, though occasionally ceasing for a few days. The tongue is coated with a thick whitish fur, and has been so for several months past. She complains very bitterly of the unpleasant taste in her mouth. The bowels are obstinately constipated, and only respond to a sharp purgative.—19th: The sight of the right eye is nearly gone. Her hearing seems affected now. When spoken to she turns her head away from the speaker, as if the voice seemed to come from a point opposite the real one. The intellect seems to be getting clouded. The general muscular paresis is more pronounced.—22d: Both pupils dilated and insensible to light. Convergent strabismus of eyes, more decided on left side; the oscillation of both eyeballs prevented a satisfactory examination with the ophthalmoscope. She can still see, but very imperfectly, with the right eye; still complains of a nasty stinking taste in her mouth. Pulse 72, intermittent. Respiration very slow, 12 in the minute. A numb feeling of "pins and needles" in both hands and feet, accompanied by a sensation of cold in the parts, is now complained of.

Jan. 31st, 1882: Pain of head continues. It now extends down the back of the neck, accompanied by stiffness of the latter. The sight of both eyes is now gone.

Feb. 16th: The vomiting has ceased since last report. Beyond a tendency to delirium at night, there is no change to record.

March 5th: Intellect more clouded; keeps talk-

ing to herself, though sensible enough when roused. The pain in the head now comes on in paroxysms, attended with slight muscular contractions of the limbs.—31st: Slowly getting worse; passes everything under her; vomiting very rarely occurs now; she has great difficulty in moving either upper or lower extremity as she lies in bed. Bedsores are beginning to form over the sacrum.

April 12th: Complete paralysis of both upper and lower extremities; has great difficulty in swallowing; is almost unconscious, answering yes to every question.—20th: Sank quietly at 1 p.m.

Autopsy, twenty-eight hours after death.—Head alone examined. Dura mater slightly adherent to calvaria in the left fronto-parietal region. Upper surface of brain healthy in every respect. On viewing the base of the brain, however, the eye is at once struck by a tumour of a dark reddish-blue color (very like a piece of placenta), lodged between the pons Varolii, whose substance it has deeply indented internally, the left lobe of the cerebellum posteriorly, and the cerebral mass anteriorly and externally. Irregularly roundish in shape, about two inches in diameter, of soft, friable consistence, it seems to spring from the upper surface of the left lobe of the cerebellum, with the pia mater of which it has a very intimate connection. The tumour was examined by a special committee of the Norwich Medical and Chirurgical Society, and pronounced to be a glioma.

Watton, Norfolk.

AN EVACUATOR FOR THE BLADDER.

By JOHN H. MORGAN, F.R.C.S. Eng.,
Charing-cross Hospital.

In a lecture published in *THE LANCET* in 1882, Sir Henry Thompson describes an aspirator which had been made according to his own design, and another modification of the same principles carried out by Messrs. Weiss & Sons, and he lays down some points as essential in the construction of an efficient instrument. The first of these principles is that "it should be light and small, so as to be easily grasped and governed by one hand"; the second requires that there should be a tap at the top for the exit of air and the introduction of water. To fulfil these conditions is not an easy matter, since any apparatus of india-rubber which is to support above a heavy tap and be attached below to a cylindrical glass receiver in which fragments are caught, and to which a catheter is attached, must be of such density and size as to be with difficulty grasped, much less compressed by a single hand, at all events many times in succession. In other words, if the continuity of the bulb is broken at two points, its resiliency must be supplied by greater thickness. This objection is practically found in the case of both these instruments. At the late meeting of the Medical Congress in London, Professor Bigelow explained that "the new and essential part of the evacuating apparatus is the large catheter, whether straight or curved," and went on to describe the various apparatus which he has contrived to extract fragments from the bladder, and at the same time to prevent the possibility of their return. These instruments were figured and described in the *Transactions*, but that Professor Bigelow is hardly yet satisfied is shown by the fact that at a recent meeting of the New York Academy of Medicine he exhibited the evacuator which he has "finally settled down upon as being the best," adding that the ball-valve and strainer which formed part of his former instrument were a "little complicated" and "apt to clog."

¹ Read before the Norwich Medical and Chirurgical Society.

Adhering to the principles laid down by these two eminent lithotritists, I have been at some pains to contrive an apparatus which should at once be effective in action, but of simpler construction than those hitherto invented. The result of my efforts is an instrument which is figured below. It consists of an india-rubber bulb (A) of moderate resiliency, and capable of containing about twelve ounces of water. This is of the shape of an inverted pear, and its narrow portion is fixed to a metal ring, which can be attached to or removed from the central portion of the apparatus by means of a screw. This is only required for convenience of carriage or for the purpose of cleaning the apparatus. In order to allow a better view of the glass-receiver, the bulb is attached at an angle slanting backwards to the rest of the apparatus, which hangs perpendicularly. The central portion is of metal, and forms one with the bulb above, and is attached by a bayonet-joint to the glass-receiver below. In front projects a short tube (D), into which the catheter—the largest of Bigelow's sizes—fits when the instrument is in use, but which can accommodate catheters of a smaller calibre. Running diagonally downwards in the interior of this portion of the apparatus, and fixed above, just at the entrance of the passage of the

the solid portion and inclined slightly backwards, the pressure of the atmosphere is sufficient for this purpose. The india-rubber bulb must not, of course, be touched until the tube (D) has been adjusted to the catheter. It will then be found that the weight of the upper and lower portions is so evenly balanced (when full) as to make all manipulation easy, and entirely under the control of one hand, so that water can be injected into the bladder and withdrawn as rapidly or slowly as is wished, and the position and direction of the catheter altered.

In using this, and all other instruments for a similar purpose, it is well, after forcing water into the bladder, to pause for a second or two before relaxing the pressure on the bulb. By so doing the fragments which have been set in commotion can settle at the bottom of the bladder, and thus come nearer the eye of the catheter, and are withdrawn by the returning current of water. In this apparatus the fragments striking against the metal disc are at once thrown down into the glass-receiver, where they remain undisturbed in any position of the instrument. The apparatus has already been used and approved by several London surgeons.

Chapel-street, Park-lane, W.

THE TREATMENT OF GONORRHOEAL OPHTHALMIA.

By CHARLES BADER,

Ophthalmic Surgeon to Guy's Hospital.

THE uniformly favorable success of this new treatment, and the serious nature of the disease, will, I hope, justify the publication of the following cases, which have occurred in the present year.

CASE 1.—Miss S—, aged eight, when seen on Jan. 21st with Dr. Harter, of Artillery-place, Finsbury-square, suffered from gonorrhoeal ophthalmia (fifth day) of the right eye, probably through a servant with gonorrhoea using a towel in the child's room. The anæsthetic was necessary for examination, the child being most troublesome; this Dr. Harter had to repeat each time when injecting the ointment. The purulent discharge, redness, and swelling of the lids were very great, and even under the anæsthetic only a glimpse of the lower margin of the opaque cornea was obtained. Similar examination on Jan. 24th and Feb. 7th showed the lower third of the cornea opaque. The ointment was injected once daily, and the eyelids kept bound with lint smeared over with it, changing the lint several times during the day. The left eye, which remained unaffected, was only bound up with lint and ointment, taking care to attend to this eye before the other was touched. The injection of the ointment was discontinued on Feb. 7th when the lids opened sufficiently to see the entire cornea. When the child was seen in March, the surface of the cornea was smooth, and the opacity reduced to a small nebula.

CASE 2.—Mrs. E. B—, aged thirty-four, was admitted into the eye ward of Guy's Hospital on March 3rd, with gonorrhoeal ophthalmia of both eyes. The lids of the right eye were too much swollen to admit of a view of the cornea; that of the left eye, on raising the red drooping swollen lid, was found to be transparent. The sister of the ward injected the ointment at 9 A.M. and 4 P.M. daily; both eyes were kept bound up with lint thickly covered with ointment; fresh lint was applied after each injection.—March 14th: Injection of the ointment at 9 A.M. only; the lids open fairly;

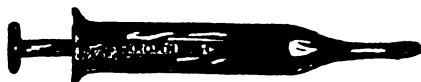

tube (D), is a perforated metal disc, which is placed in such a position that anything carried through the tube (D) must directly impinge upon it, and be thrown downwards. The glass-receiver (C) is made to fit closely to the central portion, and is shaped like the handle of a pistol, with two objects—partly because by this curve an interruption is made of any current of water carrying with it fragments of detritus, and partly because in the forepart of this transparent bowl the size and quantity of the fragments can be seen and estimated by the operator.

In order to fill the apparatus, the receiver (C) must be detached and filled, and the air driven out of the upper portion under water. The two pieces being filled, must be fixed under water, which can be done in a large basin or bucket, and for security the forefinger should be placed over the mouth of the tube (D), to prevent the escape of any water, although if the instrument is held by

the lower margin of the right cornea is opaque.—
 11st: Discharged. Advised to smear some of the ointment among the eyelashes at bedtime.—April 4th: All discharge ceased; right corneal opacity barely noticeable.

CASE 3.—Mr. H—, aged twenty, when seen on April 26th, 1882, with Dr. Blades, of Kennington-park-road, was suffering from gonorrhœa and from gonorrhœal ophthalmia of the left eye. No inspection of the cornea was possible, the swelling and tension of the eyelids being too great; there was much purulent discharge, pain, and intolerance of light. Right eye not affected. Dr. Blades injected the ointment daily (about 11 and 4 o'clock) beneath the upper eyelid of the left eye; both eyes were kept bound up with lint and ointment.—April 30th: Less pus and swelling; eyelids of a dark blue-red hue; the lower part of the cornea, as far as visible, opaque. On receiving a telegram the next day that the right eye was also inflamed and discharging, I replied, "Inject both eyes." Five days later the discharge from the last attacked eye had greatly subsided. As the lids opened and discharge and swelling became less, the injection was made once daily, but the bandage with lint and ointment was discontinued. On May 25th the ointment was continued and weak alum lotion used for bathing. In July I saw the patient: both cornea were clear, and the eyes well in all respects.

Remarks.—The ointment consists of one grain of the red oxide of mercury (supposed to destroy the contagious matter), of one-fifth of a grain of daturin or atropin (to combat iris complications), and of one ounce of vaseline (as the best vehicle to touch and saturate the entire surface of the conjunctiva with the remedies). In no case, however

great the swelling of the eyelids and conjunctiva, has any difficulty been experienced in injecting the ointment. For injection a small glass syringe, figured above, is used (made by Messrs. Krohne & Sesemann) with a flat nozzle, to pass readily beneath the margin of the upper eyelid. The ointment, passing beneath the margin of the upper eyelid, escapes, generally with some pus, at the inner canthus. About two drachms of the ointment suffice for one injection. No pain whatever is felt when manipulating gently.

NEW SPLINT-REST FOR SYME'S AMPUTATION.

By HENRY A. LEDIARD, F.R.C.S., Eng., etc.,
 Surgeon to the Cumberland Infirmary.

THE accompanying woodcut represents a splint-rest which has been made for me by the infirmary joiner under the direction of Mr. A. Proffitt, our house-surgeon at present. I have remarked that the ordinary straight back splint, although most valuable in many amputations, fails to give support, if necessary, to the heel-flap in Syme's amputation. I allude to cases where the stitches are subjected to strain, and to cases where union of the flaps is delayed from some cause, and where adhesive plaster is employed after the stitches have been taken out. Again, in the usual dorsal position of the body after Syme's amputation, the cut end of the tibia tends to project somewhat from the drooping of the heel-flap, which is some-

times more bulky and heavy than at others, according to the nutrition of the patient and amount of tissue available. I have lately tried the effect

of a wooden splint so shaped as to fit the end of the stump and support its side and end. In order to promote drainage and to relieve tension, my old master, the late lamented Professor Spence, was in the habit of placing his Syme's amputations upon their sides and bending the knee. The discharge would thus drain through the outer angle of the flap, near where the tip of the external malleolus had been. This is an excellent method in some instances, if the lateral posture is tolerated, but the stump has occasionally a tendency to slew round, and to require readjusting with plaster. I consider, then, that the splint-rest figured will afford another step towards that rest and freedom from pain so essential in the treatment of wounds, which Hinton and Callender both taught and practiced.

There are some Syme's amputations which do not require a thought from the moment of the completion of the operation, even strapping after removal of the stitches being wholly unnecessary; but it is not so in all, and whether the latter are treated with Listerism or the open method, I think that in a few cases my splint will be found serviceable. It will be observed that the splint is hollowed for the calf, as well as shaped for the stump end.

Carlisle.

A NEW INTRA-UTERINE STEM, COMBINED WITH AN INSTRUMENT FOR KEEPING SEPARATE THE LIPS OF THE CERVIX AFTER INCISION.

By J. BERESFORD RYLEY, M.D.

It will, I think, be admitted without question that dysmenorrhœa and its wide-spreading effects solicit the attention of the profession more frequently than all the other diseases of the uterus put together. Any new mechanism therefore that has for its object the further alleviation of a malady so distressing, on account of its physical, physiological, and psychological consequences, will, I feel sure, be received with that consideration which its importance deserves. The idea of making the cervix uteri the *point d'appui* or fulcrum for an intra-uterine stem, instead of the vagina or a

point outside the body as has hitherto been the case, had been present to my mind in an indefinite shape for a long time, and is only the extension of another which had for its object a contrivance for keeping separate the lips of the cervix after incision. Those who have been called upon to perform this operation and all who have written on the subject are aware and assert that a successful issue depends altogether upon the tedious after-treatment and is but little affected by the mode of

operating. Dr. Atthill, of Dublin, than whom no one has written more practically upon this point, says in his "Diseases of Women," "Passing the uterine sound daily for at least two or three weeks subsequent to the operation and at intervals for some time longer, I find to be usually sufficient to prevent the divided surfaces from uniting." If one will but pause for a moment to consider the almost unbearable distress to the patient and the humiliating tedium to the practitioner involved in such a proceeding, it will not be wondered at that so many should have pronounced this operation to be most unsatisfactory. I have examined the cervix uteri after operation by most of the well-known gynecologists in London and elsewhere, and have usually found that after a time its canal and outlet had contracted back to their originally abnormal conditions, and that the history of the majority of the patients was that they had had more or less relief for a few months after operation, but that the pre-existing symptoms had returned as severely as ever. Again, those who have had any experience in the application of the various forms of uterine pessaries must very often have felt extremely disappointed with their general results, and will, I think, agree with me that not one-tenth of the patients for whom they are used obtain any marked benefit therefrom. Intra-uterine pessaries undoubtedly give much better results, but their mechanism hitherto has been so complicated and imperfect as to render their introduction and retention both difficult and distressing. I hope, however, that the instruments that I now submit to the profession will be found to obviate all the difficulties and distresses that I have enumerated. Their mode of application is so easy and the principle on which they are based so simple, that a glance at the diagram will be sufficient to indicate this without any tedious details on my part. It may be objected that an intra-uterine stem as applied in this manner will not alter any abnormal axis of the uterus; but I do not think that this is a matter of any great consequence, because the chief objects, I think, to attain by this mode of treatment are to straighten the organ in question and keep its canal pervious. It also may be thought that the metal pins on which the instruments are based might set up irritation at the points of puncture and easily tear through the structures, but I can answer from experience that neither of these objections will be found to be realized in practice, and that they can be worn for months without inconvenience. I hope that those who, like myself, make a special study of the diseases of women will give these instruments, which are made for me by Messrs. Krohne & Sesemann, of Duke-street, Manchester-square, a fair trial, and kindly acquaint me with the results of their experience.

Finsbury-square, E. C.

NOTES ON MEASLES.

By WALLACE B. CROSBY, L.R.C.P.I., etc.

I HAVE before me notes of many cases of measles which came under my own observation, and having taken those notes with the special object to, at one time, define clearly for myself, and possibly for others, special points in the disease, I think that I might now draw attention to the points I arranged my notes to make clear. The first points in the disease to which I wish to call attention are the slight amount of exposure to contagion necessary to contract it, and the early period at which infection may be given off.

W. C—, the son of a medical man, was sitting at home when his father entered the room, having come straight from a case of measles. The latter, forgetting that he had omitted to take the usual precaution to disinfect his hands, bent over the son and stroked his face several times. Suddenly he remembered the case he had just left and his sin of omission, and at once passed over the boy's face a towel sprinkled with a solution of carbolic acid. W. C— sickened in ten days with measles. This case will illustrate the slight amount of exposure necessary, and the communication of the disease through a third person. C. D— drove in the same cab with W. C— to school; on the same day W. C— came home early, shivering, and with a temperature of 101°. On the morning of the fifth day, or ninety-six hours after invasion, the rash of measles developed on W. C—. In the course of ten days C. D— sickened. This will illustrate exposure on the very first day of invasion, followed by the communication of the disease. I have had many cases which came under my observation before the eruption where, suspecting measles coming on, I had complete isolation with the usual disinfecting precautions observed, and yet the disease developed in due course among other members of the family.

Period of Incubation.—I have seen various statements as to this, some writers on the subject giving a much longer time than I have yet observed. In the great majority of my cases nine to ten days after the exposure the premonitory symptoms set in. I have some where eleven days, and a few where twelve days, elapsed before the disease showed itself. I am disposed to think that the long period is where the patients have more resisting powers, as my cases of twelve days, whether accidental or otherwise, were the parents who took it from their children. I think the one exposed to contagion, after a quarantine of fourteen days, may, in the vast majority of cases, be declared to escape the disease, if he or she has a normal temperature and none of the symptoms after the lapse of that interval.

Period from Invasion to Eruption.—This period I consider full of interest, the special points being the temperature and the day of eruption. The disease occasionally sets in with a temperature of 101° or higher. Frequently on the second day, especially in the morning, the temperature has gone down to normal; so that at this stage, when sometimes the other symptoms are badly marked, the ailment may be declared—unless one has considerable experience in the course of measles—to be simply a feverish attack now passing off. On the third day, however, the temperature again rises, and the symptoms become more obvious. The highest temperature is usually reached about twelve hours before the eruption, at the eruption, or twelve hours after the eruption begins to come out. A temperature of 103.5° I should set down as the average at this period, though I have frequently seen 104°, and occasionally 105°. I have watched several cases from day to day, and have notes of two cases where no eruption whatever appeared till the morning of the fifth day, or ninety-six hours after the first rise of temperature was observed. Occasionally, however, I have seen it make its appearance at the close of the third day, but much more frequently on the morning or evening of the fourth day—that is, from seventy-two to eighty-four hours after invasion. I have dwelt on these two points more especially, as one does not often see cases of measles till the eruption has already appeared, and my object has been to show that, notwithstanding the temperature occasionally falling to normal twenty-four hours after invasion, or notwithstanding four entire days elapse—

ing without rash, still measles is in no way contra-indicated.

Eruption to decline.—The temperature generally falls rapidly once the eruption has well appeared. In from twelve to twenty-four hours after the highest temperature has been reached I have seen a fall of from three to four degrees frequently, with possibly a subsequent rise of a degree or two twelve hours after. Normal temperature in an uncomplicated case is reached on the seventh or eighth day after invasion. The respiration should always be counted as the time for eruption approaches, and for a day or two after it has already approached, and the chest occasionally examined. The respiration about this period may number thirty, thirty-five, or even forty, without any bronchitis or pneumonia being present; but any greater number, unless the temperature is very high, will usually indicate some chest complication. I say unless the temperature is very high, because I have seen from fifty to sixty respirations per minute due to a temperature of 105°, where no abnormal condition of the lungs or bronchial tubes existed.

Isolation.—This, with the usual disinfecting precautions, ought to be commenced as early as possible, and carried on for some time after the eruption has disappeared. I generally advise at least a week to elapse after the fall of the temperature to normal, or the entire disappearance of the rash, before I allow my patient to see anyone other than those engaged in nursing. During this interval the patient has a couple or three baths, using carbolic soap freely. I think, then, after the room and clothes have been disinfected, all contagion is gone.

There is one misleading symptom occasionally present in the early stages to which I wish to direct attention. I refer to the character of the cough. I have seen it of such an exceedingly croupy nature that croup and not measles might be looked for. I had one case, indeed, followed by croupous or plastic bronchitis, where—the measles having subsided—casts of the bronchial tubes were expectorated; but, as a rule, the cough, in the cases where it is croupy, loses this distinctive character after the eruption has come well out.

Downpatrick.

DEATH AFTER ABDOMINAL OPERATIONS FROM HEART-CLOT, DUE TO DISEASE OF THE KIDNEYS.

By LAWSON TAIT, F.R.C.S. Eng.

DEATHS after any kind of abdominal operation are now becoming so rare, from the elimination of preventable causes, that we seem likely to gain an insight into causes which are not preventable. Amongst these, in my recent experience, the most prominent has been heart-clot. In deaths after ovariectomy it seems to be clearly associated with the impoverishment of the blood resulting from repeated tapplings. But it has occurred to me twice lately in other cases, where tapping was not an element. One was a case of removal of the uterine appendages for chronically inflamed and adherent ovaries, and the other was a case of removal of a pediculated myoma. The patients were respectively forty-one and fifty-one years of age, and in neither of them did examination of the urine give any evidence of disease of the kidneys. They both died in the same way thirty-six hours after the operation, the only feature being an extremely rapid rise of the pulse beginning in about twenty hours. The conditions found after death were precisely the same; adherent clot in the heart

chambers and (to quote the words of Dr. Saundby, who made the post-mortem examinations) "both kidneys small, the capsules adherent, the cortices narrow, not more than one-eighth of an inch in breadth." The details of the operations were found to be quite satisfactory.

The facts of these two cases are too closely identical to form a mere coincidence, and from my past experience I feel strongly that, but for the condition of the kidneys, they would both have recovered.

I write this note to ask help from those who are familiar with kidney troubles upon two points: Could I have discovered, in any way at present unknown to me, the state of the kidneys, and could I have done anything in the way of preparatory treatment to prevent the formation of the heart-clot? I have removed tumours, in many instances, knowing of the existence of serious visceral disease, including Bright's disease, and the patients have recovered. But in this (to me) unrecognizable kidney atrophy there seems to be a serious bar to operative success.

Birmingham.

NOTES ON CONCUSSION OF THE SPINAL CORD AND BRAIN.

By WM. SCOVELL SAVORY, F.R.S.,

Surgeon to St. Bartholomew's Hospital.

Is the current view of the immediate cause of the paralysis which follows a severe injury, as a fracture, of some portion of the spine, a correct one? Can the loss, not only of voluntary motion and sensation, but also of excito-motor reflex power in the part below, which is the usual effect, be directly due to pressure on some limited portion of the cord by the fractured bone? In experiments on animals, when the spinal cord is divided at any point, after the shock of the operation has passed off—and this is significant—the power of reflex action in the part below, as everyone knows, remains. Why, then, is it abolished after fracture? Is it not that the violence which is sufficient to produce fracture is severe enough to produce such concussion or disturbance of the cord below as to destroy its power as a nerve centre? Instead of the common statement that the loss of reflex function is due to pressure at a particular part, would it not be more correct to say that the loss of reflex power below is the result of violence which at the part where it was directly applied was sufficient to break and displace the bone, but which has also injured the cord beyond? At all events, if the loss of reflex function be due to the fracture, it must be indirectly; to some mischief by displacement or dragging inflicted along the cord, of course far beyond the part directly implicated in the fracture; but, at least in many cases, the evidence strongly points to concussion as the cause. In a few exceptional cases, although compression of the cord by the displacement of the fractured bones continues, the portion below recovers its function as an independent centre, for the power of reflex action in the lower limbs is, after awhile, restored. The extension and persistence of mischief beyond the seat of visible injury surely claim more consideration than they have hitherto received. But in any case it is not clear why the part above does not to a greater extent lose its reflex power. One would imagine, I think, that the effect of such injury would usually extend almost equally, as indeed it occasionally does, in both directions. How is the clinical fact to be explained?

The curious fact that in concussion of the brain not only may there be a complete loss of consciousness for a considerable period after the injury, but

that in some cases after complete recovery there may be total loss of memory of all events which have happened shortly before the injury, has not perhaps received the attention it deserves. The following cases may be taken as examples.

The driver of a hansom cab was knocked off his box by an omnibus at the top of Newgate street, and brought to the hospital in a state of complete unconsciousness from concussion. From this he speedily recovered; but, at least for several weeks after, when he appeared to be in every respect quite well, he could not in the slightest degree recollect what he had done or seen, or where he had been in the half hour immediately before the accident. It was known that within that time he had taken up a passenger at Cornhill, and driven along Cheapside and Newgate street, yet of this he never had the faintest recollection; but for all events up to this time his memory was excellent.

Again, a gentleman was thrown from his pony at polo, and picked up quite unconscious, in a state of concussion. He recovered from this in the course of two or three hours, and in a few days was as well as ever. But he could never recollect some striking events in the game which occurred within half an hour or so of the accident; yet up to this blank period his memory was minute and accurate.

Now, what happens in such a case? I suppose no one can tell. The substance of the brain is shaken, and presumably for a time damaged in some way or disturbed; or, as we may say, its nutrition is temporarily impaired, and thus may subsequent loss of function be accounted for. The recollection of a bygone event shows that some impression which the brain receives at the time has been registered; and this must be, I suppose, by some change, however subtle, which is more or less durable. Does the violence of the concussion somehow interfere with the registration of such change; wiping out, as it were, the record before the ink is dry? But such guessing as this only shows how very far I am from understanding the fact.

ANOTHER NEW TEST FOR ALBUMEN.

By GEORGE JOHNSON, M.D., F.R.S.,

Professor of Clinical Medicine and Senior Physician to King's College Hospital.

My son, G. Stillingfleet Johnson, in a paper published in the *Journal of the Chemical Society* (August, 1874) describes some compounds of albumen with the mineral acids, and gives a table showing the action of various chemical reagents in causing coagulation in solutions of these albumen compounds. He found that only two reagents besides the mineral acids cause the coagulation of albumen in solutions of all its acid compounds—namely, baric chloride and picric acid—and he suggested to me that the latter of these two substances might be found a useful test for albumen in the urine; for while the baric chloride could not be added to normal urine without being precipitated by many of its normal constituents—sulphates, carbonates, and phosphates—picric acid causes no precipitate in normal urine.

Acting upon my son's suggestion, I have for some months used a saturated solution of picric acid as a test for albuminous urine, with results which may be briefly stated as follows: In normal urine it has never given a precipitate or produced any other change than the slight yellow tinge due to the color of the solution, the mixture remaining quite transparent. When heat and nitric acid, applied with the usual well-known precautions,

have shown the presence of albumen, the picric acid solution has invariably caused coagulation in proportion to the amount of albumen.

Most clinical observers are agreed that one of the most delicate tests for a minute quantity of albumen consists in the addition of nitric acid to the cold urine, when a cloud appears at the junction of the two liquids. In applying this test the urine may be poured upon the acid which has been previously placed in the test tube, or the urine having been poured into the test tube, a few drops of the acid are allowed to flow down the side of the tube while held in a sloping position. It sometimes happens that when the amount of albumen is very small an interval of some minutes elapses before any change occurs at the junction of the two liquids. Now, in such cases I have found that a mixture of equal volumes of the urine and the picric acid solution has immediately become turbid with coagulated albumen. In this speedy and decided action of the test upon urine which is only slightly impregnated with albumen, the picric acid solution is superior to nitric acid. In applying this test it should be borne in mind that the picric acid saturated solution is but little heavier than distilled water, its specific gravity being about 1003; so that, unlike the heavy nitric acid, it tends when slowly poured into the tube to float on the surface of the urine, where a film of coagulated albumen forms at the junction of the two liquids. This floating film with the picric acid solution forms a pretty contrast with the film near the bottom of the test tube when nitric acid is the reagent employed. The coagulum formed with the picric acid solution in cold urine requires a very large excess of water for its solution; in fact it is about as insoluble as the coagulum produced by nitric acid. The picric acid coagulum is readily soluble in caustic potash and ammonia; if, therefore, albuminous urine be alkaline it will require to be neutralized or acidulated before applying the picric acid test; but in all my numerous testings with the picric acid I have not once found it necessary to acidulate the urine. One result, then, of my industrious son's purely scientific work at these compounds of albumen has been to supply us with a really valuable addition to our tests for albumen in the urine.

Then it has lately occurred to me, what is obvious enough when once attention is directed to it, that for a saturated solution of picric acid the crystals or the powder may sometimes be substituted with advantage. A small crystal added to the albuminous urine quickly dissolves and as quickly coagulates the albumen. The crystals are permanent in the air, and may be kept for any length of time without undergoing change; and I venture to predict that a few of these crystals in a small bottle will speedily take the place of nitric acid, whether in sealed tubes or in bottles, in all urinary test cases which are made for carrying in the pocket. With picric acid powder or crystals in one bottle, and Cooper & Fehling's test pellets in another, the most complete urinary test case need contain no other liquid than the spirit in a small tubular spirit lamp. I have for some years carried in my case nitric acid in a well-stoppered and capped bottle, and then enclosed in a boxwood box; but I now with a sense of relief replace the destructive liquid acid for the entirely harmless solid.

Since the preceding was written I have met with two specimens of urine suspected to be albuminous, in which picric acid caused a decided opalescence, while nitric acid only darkened the color of the urine. I am therefore confident that in some cases picric acid will prove to be a more delicate test for a mere trace of albumen than nitric acid. In the solid form the powdered picric acid has this

advantage over the crystals, that it dissolves more rapidly.

Savile-row, W.

PURULENT DISEASE OF THE EAR;

PRODUCING CEREBRAL ABSCESS, PURULENT MENINGITIS, AND OBLITERATION OF THE RIGHT LATERAL SINUS, WITH STRIKING CHANGES IN THE INTERIOR OF THE TEMPORAL BONE.¹

By THOS. BARR, M.D., F.F.P.S. Glas.,

Lecturer on Aural Surgery, Anderson's College, and Dispensary Surgeon for Diseases of the Ear, Western Infirmary Glasgow.

W. C—, a boilermaker, aged thirty seven years, was a remarkably strong man, of great muscular development and of medium height, weighing in ordinary health between fourteen and fifteen stones. He suffered from purulent disease of the right ear from the age of twelve till his death—that is, for twenty-five years. There was almost total deafness on the affected side. The disease was supposed to have originated in the blow of a cane received on the right side of the head, and inflicted by a schoolmaster by way of chastisement. This injury was followed by great pain, continuing for several weeks and culminating in the formation of an abscess which was opened behind the auricle. About the same time a discharge of matter appeared from the external auditory canal. The purulent discharge from the opening behind the ear continued, with variations in quantity, till six years ago, when the opening closed, leaving behind a depressed cicatrix. The discharge from the canal of the ear, which had usually an offensive odor, continued, with slight intermissions, till the patient's death. It was slighter, however, during the nine months before his fatal illness. He was liable during cold weather to attacks of hoarseness with sore throat. At the age of seventeen he suffered from acute inflammatory attacks in the right ear, when it was supposed that his life was in danger. He noticed that when the discharge ceased for a short time he suffered from severe headache, and became very dull and fretful. Indulgence in alcoholic stimulants produced the same effects, and he was therefore very temperate in their use. In the middle of November last there began a series of morbid processes—first in the left ear, then in the right—which in the course of three months terminated fatally by extension of the purulent inflammatory process to the interior of the cranium. The left ear, which previously had been always healthy, and in which he enjoyed good hearing, became at that time dull and discharged slightly without any distinct pain. This was associated at the beginning with sore-throat and hoarseness. The dulness and slight discharge in the left ear continued for two months, at the end of which an acute inflammatory process began in the ear. While at work on Monday, Jan. 23rd of this year, and particularly on his way home at the end of the day, he experienced great giddiness, so that at times he staggered in walking. On the following morning at four o'clock he awoke with severe pain in the head, with great giddiness, and he looked deadly pale. Dr. McConville was sent for in the forenoon, when he found the patient "suffering from great pain on both sides of head, but chiefly on the left side. The left auricle projected abnormally from the side of the head, and the meatus was almost closed by swelling of its walls. There was a general feeling of uneasiness

and tenderness in the temporal and mastoid regions. The cervical glands immediately behind the lobule were much swollen and painful." The deafness on the left side was now almost as complete as on the right, and only the shrill voice of a female friend exerted at its highest pitch close to the left ear could be heard by the patient. Dr. McConville then, for the first time, examined the right ear. He found over the upper part of the mastoid region, a little distance behind and above the auricle, a depressed cicatrix adhering to the subjacent bone. The canal of the ear was filled with pus, and on its removal by syringing with warm water a few granulations were seen at the inner end of the canal. There was some bronchitis and pharyngeal catarrh, along with febrile disturbance and thickly coated tongue.

The treatment carried out by Dr. McConville consisted in the local abstraction of blood by leeches applied in front of and below the left auricle, in the use of poppyhead fomentations and hot linseed-meal poultices to both sides of the head, and in the use of a gargle of chlorate of potash. The general treatment included catharsis by jalap and calomel, followed by the use of a mixture containing iodide of potassium, chloride of ammonia, and an anodyne for the cough. After a few days a large cantharides plaster was applied to the back of the head, from ear to ear, with apparently considerable relief to the pain and the giddiness. The man's condition seemed to improve. After a few days the painful symptoms passed off, and the hearing was partially regained in the left ear. This improvement continued, exciting lively hopes of recovery, which were, however, changed to bitter disappointment, for in the course of another week grave and ominous symptoms appeared.

On Saturday evening, twelve days after the first attack of giddiness, the patient experienced a sense of chilliness; pain was complained of, not on the left, but on the right side, the seat of the old purulent disease. Dr. McConville then ordered forty grains of bromide of potassium and ten grains of chloral to be taken night and morning. The next morning the man felt so well that he proposed to take a walk in the West-end park; but to this the doctor distinctly objected as a possibly dangerous exposure to cold. That evening he had another chill. From this day the symptoms became most grave, and indicated serious mischief in the interior of the cranium. The pain in the head—chiefly in the front—became daily more intense. Nights were passed in agony, which anodynes, externally and internally applied, only partially mitigated. The patient was seized with repeated rigors. In these rigors the arms and legs shook violently. These rigors or shakings soon took the character of epileptiform convulsions.

I was asked by Dr. McConville to see the patient on Wednesday, Feb. 15th, seven days before his death. The man then lay in a stupor, but was capable of being roused; there was extreme deafness, loud shouting into the left ear being necessary before he heard and understood. I asked him about the pain in the head. He answered, slowly prolonging the word, "excruciating." I found no tenderness in the right ear, or in its neighborhood. The orifice behind the ear was now open, and fluid injected into the opening passed quickly and freely through the canal of the ear. The current could also be forced as easily in the opposite direction. Disinfecting fluids were afterwards regularly and frequently forced through the ear by this means. It was apparent, however, that the mischief was in the interior of the cranium, and a cerebral abscess was diagnosed. Up till four days of his death he was able at times to get out of bed, and even to walk from the room to the kitchen.

¹ I am indebted to my friend Dr. McConville, the medical attendant of this patient, for the chief facts given in the clinical history.

Four days before death he was seized with paralysis of the left arm and leg and right side of the face. For two days before death he was quite comatose. He died on the evening of Wednesday, February the 22d, about a month after he left his work and sixteen days after the more definite brain symptoms set in.

The autopsy was made by Dr. James Alexander Adams, twenty-four hours after death. Under the calvaria the veins of the dura mater were seen to be torpid. On clipping away the exposed dura mater the middle part of the upper surface of the right cerebral hemisphere presented a slightly bulging appearance, but the surfaces of the hemispheres appeared to be otherwise normal. At this stage of the examination no unusual odor was apparent from the intra-cranial contents, but while removing the brain from the base of the skull, when the right temporal lobe was raised from the middle fossa of the skull an extremely disagreeable fetid odor was suddenly experienced. A small quantity of purulent matter was at the same time seen on the floor of the middle fossa of the right side. The brain being placed with its base upwards, the lower surface of the right temporal lobe corresponding with the upper surface of the petrous part of the temporal bone was seen to be dark in color and very soft to the touch, but having no apertures in its substance. On cutting into the temporal lobe at this part, however, a thin brownish fluid, emitting a most offensive smell, poured out in considerable quantity; and on making further sections, the lateral ventricle and a great part of the interior of the right cerebral hemisphere seemed to be occupied by this fluid. There was no distinct boundary wall or membrane enclosing this collection of fluid, but the substance of the brain around seemed in a softened, at some parts

thickened than elsewhere. The bone beneath was dark-colored and eroded; at one part it was perforated by a considerable carious opening communicating with the antrum mastoideum. After a time the color of the bone changed, and instead of being dark, it assumed a bleached and white appearance. Behind, the dura mater covering the concavity for the lateral sinus, and forming the walls of that sinus, was extremely thickened and converted into a fleshy mass. The lumen of the lateral sinus was completely obliterated by thickening of its walls and by fibrous adhesions of its inner coats. Some purulent matter was found infiltrated between this thickened mass and the bone forming the inner wall of the antrum mastoideum. This osseous wall was found to be very thin, very much eroded on its inner surface, and perforated at one part by an opening leading to the antrum mastoideum. On the outer surface of the mastoid process just behind the root of the zygoma, and about ten millimetres above and behind the external orifice of the osseous part of the canal of the ear, there was an opening in the bone four millimetres in diameter, which communicated at a distance of five millimetres with the antrum mastoideum. The bone, perforated by this channel, was dense and hard as ivory. On examining the osseous part of the external auditory canal, the posterior wall was found extremely thinned and perforated by three small apertures. This extremely thin perforated plate of bone formed a partition between the external auditory canal and the dilated antrum mastoideum. At the inner end of this posterior wall there was a large semilunar gap, with the convexity outwards, which passed into the antrum mastoideum. A vertical antero-posterior section through the middle ear exposed a very unusual condition of the tympanum and mastoid cells. The whole of the normal contents of the tympanum were gone; there was not a vestige of the tympanic membrane or ossicular chain remaining. There was complete osseous closure of the fenestra ovalis. The fenestra rotunda, however, still remained. The promontory and floor of the tympanum were covered with soft granulation tissue. A white nipple-shaped hyperostotic growth, with two or three vertical grooves, occupied the position of the outer and inferior semicircular canals. Above that an excavation extended inwards nearly as far as the posterior surface of the petrous bone. The bone forming the floor of the tympanum was enormously thickened (twelve millimetres in thickness), and very dense. The mastoid cells had undergone a remarkable change. The antrum mastoideum was immensely dilated, forming a cavity two and a half centimetres long from within outwards, and nearly two centimetres from the back wall of the external auditory canal to the thin cortical layer separating the antrum from the groove for the lateral sinus, while it measured in height more than one centimetre and a half. The outer wall of this cavity was smooth and white, while the inner one was lined with granulation tissue. The mastoid cells proper were sclerosed and completely obliterated and, instead of large numbers of air-filled spaces, as in the normal condition, I found extremely hard, dense, ivory-looking bone, through which I had great difficulty in working the saw. The two cavities, the tympanum and the greatly dilated antrum mastoideum, were filled with thick curdy matter, having a most fetid odor. Left temporal bone: The dura mater over the petrous part was normal. The osseous roof of the middle ear was also apparently free from pathological change. On examining the tympanic membrane I found a small round perforation, about two millimetres in diameter, in the posterior part of the membrane

even gangrenous, condition. The temporal bones were removed for careful examination. Right temporal bone: The dura mater covering the upper surface of the petrous part of the bone was swollen, soft, and pulpy, and was perforated by two small apertures. The portion of dura mater covering the roof of the antrum mastoideum was more

flaccida. This opening was partially closed by granulation tissue. On removing the roof of the middle ear I saw that the head of the malleus and the body of the incus were gone, and that the opening in the membrane communicated with the antrum mastoideum. The latter cavity was filled with muco-purulent fluid. The osseous layer forming the floor of the tympanic cavity was only about two millimetres in thickness, markedly contrasting with the right side, where the floor of the tympanum measured twelve millimetres in depth.

tion of the sinuses of the brain, Wreden gives as his experience that 14 per cent. of purulent ear disease are complicated by thrombosis of the sinuses of the interior of the cranium, while Dusch found that out of thirty-two cases of thrombosis of these sinuses twenty originated in purulent disease of the ear. Of the venous sinuses of the brain the lateral is much the most exposed to injurious influences from the ear. This is due to its anatomical connection with the mastoid cells. In the deep concavity of the groove for the lateral sinus only a thin osseous partition separates the

Remarks.—In this single case we have an illustration in the side right of almost all the various consequences, both to the ear itself and to the interior of the cranium, following upon chronic purulent disease of the middle ear. The changes produced in the ear itself were: (1) Total loss of the tympanic membrane and ossicular chain; (2) osseous closure of the fenestra ovalis; (3) great dilatation of the cavities of the tympanum and antrum mastoideum; (4) conversion of the cellular structure of the mastoid cells into dense tissue of almost ivory consistence; (5) the formation of six carious apertures opening into the dilated antrum mastoideum—namely, two communicating with the interior of the cranium, one perforating the outer wall of the mastoid process, and three passing into the external auditory canal. The changes produced by extension of the disease to the interior of the cranium were also very remarkable. The brain, the dura mater, and the lateral sinus were all three involved in serious morbid changes, including cerebral abscess, purulent meningitis, and changes in the lateral sinus producing closure of that channel. We have thus represented in this case all the morbid processes known to be the chief modes in which disease of the ear leads to a fatal issue. It is undoubtedly very rare to find the whole three present in the case of one patient. The condition of the lateral sinus is probably the most striking and interesting feature in this case. No doubt some degree of phlebitis of the lateral sinus is a not unfrequent complication of purulent disease of the middle ear. The mischief is, however, probably in most cases limited to some thickening of the walls of the sinus, and to a consequent diminution of its lumen. In regard to the frequency of the implica-

mastoid cells from the walls of the sinus. This partition is always perforated by openings for the passage of connective tissue, vessels, and nerves. Besides, it is not only frequently so thin as to be transparent, but it is no very uncommon thing to find it containing small gaps, in which case the mucous lining of the middle ear and the wall of the sinus are in direct contact. In the case before us the state of this osseous partition, eroded and perforated by carious disease, affords a ready explanation of the mode of extension of the disease in the ear to the walls of the lateral sinus. But without such disease of the bone the simple juxtaposition of the lateral sinus with the ear is in suppurative disease a source of great danger. All surgeons know that phlebitis and thrombosis are very apt to form in the vessels of a tissue which is the seat of purulent inflammation. When therefore, as is frequently the case, the lining of the mastoid cells is chronically inflamed, softened, or eroded, and when these cells are filled with decomposing purulent matter, emanating gases of putrefaction, is it surprising that phlebitis and thrombosis with their effects should be set up in this large venous trunk, so closely contiguous to and so connected by bloodvessels with the diseased part? More frequent extension of disease in the middle ear to the lateral sinus would take place but for two obstacles opposed by nature to such extension. First, the natural power of resistance presented by the strong tissue of the dura mater, which forms the walls of the sinus, even when this dura mater is in actual contact with a diseased part. In such circumstances the walls of the sinus may become merely thickened without further mischief. For example, necrosed and carious bone has been found in contact with the

walls of the lateral sinus, without more mischief than some thickening of the walls of the latter. Secondly, the thickened lining membrane of the middle ear, together with the thickened osseous walls of the latter, circumscribes the morbid process in the ear and frequently forms an important barrier erected by nature against the invasion of this great venous channel of the brain by the disease in the ear. This case is one more added to the large record, which the literature of this subject presents, of fatal results arising out of old and neglected purulent disease of the ear. It is to be feared that, in spite of this dismal record, chronic purulent disease of the middle ear, frequently manifesting itself by the single symptom of a discharge from the ear, is still viewed in too many cases with indifference by the profession as well as by the public.

REMOVAL OF MALIGNANT TUMOUR OF THE NECK,

INVOLVING THE STERNO-MASTOID MUSCLE AND INTERNAL JUGULAR VEIN.

By G. H. HUMZ, M.D.,

Surgeon to the Newcastle-on-Tyne-Infirmiry.

SOME years ago attention was drawn to the subject of removal of tumours of the neck by the late Professor Spence, who published two successful cases in which the mass removed was of great size. Mr. Spence pointed out the necessity of carefully determining the nature of the tumour before undertaking such operations, and laid stress upon the signs which distinguish growths of a non-malignant from those of a malignant character. At the time Mr. Spence published his cases he had been able to discover the record of only four similar operations by British surgeons. His cases served to demonstrate the practicability of the removal of even very large tumours underneath the sterno-mastoid when these are of a non-malignant nature, and therefore more or less completely encapsuled, and such operations have frequently been successfully undertaken since. In the case of malignant growths in this situation, on the other hand, it is usually laid down that they ought not to be interfered with. But to this rule there are exceptions, and an attempt at removal seems to be justified whenever recent origin, fairly defined limits, and comparative mobility, render it probable that the growth can be entirely extirpated.

The following case is recorded as an instance of such a tumour which though involving important parts admitted of complete and, so far as can be judged, successful removal.

Mr. B—, steamboat owner, aged sixty-six, was sent to consult me in March last by Dr. Peart, of North Shields, on account of a tumour of the left side of the neck. It had been noticed four months, and was increasing rather rapidly. It had been occasionally the seat of pain, and beyond a slight interference with swallowing did not cause other inconvenience. There was no engorgement of the veins of the face. The growth, which was hard and nodular, extended from the level of the upper border of the thyroid cartilage to the clavicle, being situated underneath and evidently involving the sterno-mastoid muscle. The limits of the tumour were defined as regards its upper, lower, anterior, and posterior margins, and the overlying skin was free, but an incomplete mobility suggested doubt as to its deep connections. The tumour was evidently malignant, and its re-

moval without delay was advised. The operation was performed on March 23rd with the assistance of Drs. Peart and E. Brumwell. An incision was made through the skin from below the mastoid process to the clavicle, and a second incision was made backwards from the first so as to obtain space. The clavicular part of the sterno-mastoid was next cut through above and below the tumour, and as the sternal portion was not involved it was separated and displaced to the front. The mass was then freed behind and inferiorly. The omohyoid was found to enter the tumour and was divided. In clearing the inferior border the dissection was pursued carefully till the deep vessels were reached. It was then found that the growth was closely connected to the internal jugular vein, and a double catgut ligature was passed round the vessel and held in readiness. Continuing the dissection upwards, the tumour was seen to be closely attached to the anterior wall of the vein for the extent of about three inches. The ligature which had been passed was therefore tied, and the vein divided. A second double ligature was in the same way applied, and the vein divided above its connection with the tumour. There was then no difficulty in separating the mass with the adherent portion of vein from the carotid artery and pneumogastric nerve, and completing its removal. The descendens noni was not seen. The patient went on well after the operation. For a few days he had difficulty and pain in swallowing, which seemed mainly due to the disturbance of parts which the act involved. The lines of incision healed almost by first intention, but discharge continued from the cavity for some time, and the drainage-tube was not finally removed till the end of three weeks.

Microscopic examination of the growth showed it to be carcinomatous. It consisted of cells of irregular form, with multiple nuclei, the cell-masses being traversed by connective-tissue stroma. There has been so far no return of the disease.

Newcastle-on-Tyne.

A METHOD OF APPLYING LIGATURES TO VEINS.

By HENRY SYDNEY, M.D., C.M.

In applying a ligature to a vein, or adopting any mode of occlusion, inflammatory action is both inevitable and requisite. The form of phlebitis required is the healthy aseptic variety, with its limiting zone of plastic formation passing across the lumen of the vein and its solidified contents and preventing purulent matter or the results of disintegration from entering the circulation. The variety to be dreaded is the septic, where phlogogenous matter, zymotic or chemical, penetrates the tissues before the defences of the limiting zone can be formed, and diffuse suppuration is the result. If septic inflammation were due only to germs introduced from without, it might be hoped that strict antiseptic precautions would prevent it, but there is every reason to suppose that it can arise from the formation and absorption of a material not of a zymotic but a chemical nature, due to decomposition or retrograde metamorphosis of tissue or wound products. According to Billroth, the surface of a healthy granulating sore or a zone of healthy plastic formation is impermeable to septic organisms, but where, from the presence of crushed or devitalized tissues, the wound is unhealthy, septic material, either formed within or introduced from without, can be absorbed into the system. Now, in the ordinary mode of occluding veins by acupressure

or subcutaneous ligature there is, in addition to the vein, a large amount of skin and other tissues seized, compressed and more or less devitalized; and consequently conditions are produced favorable to unhealthy tissue metamorphosis and absorption. This may appear a theoretical rather than a practical view, or a refinement of the septiphobia, now so extensively prevailing in the surgical portion of the profession, but it is nevertheless a very palpable possibility, if not probability, and one which, in view of the still questionable reputation of operations of complaisance on veins, cannot be allowed to pass unheeded. But from whatever point it is viewed, the principle of enclosing within ligature or compression tissues other than the vessel to be occluded is wrong, and whatever proceeding tends to limit the action of the ligature to the vessel only, excludes an element of danger. Whether the dangers of operation on veins are exaggerated or not, it is easily conceivable how on these busy highways of the system results are apt to follow grave in proportion to the ease with which, ceasing to be local, they become general, and therefore an essential precaution in operations is antiseptic procedure. A punctilious regard to cleanliness may obviate the employment of the redundant ceremonial of full antiseptic measures. Either the spray or the irrigator may be used. I have, when operating by ligature, had equally good results from both. I have also had perfect freedom from suppuration and sepsis, without either spray or irrigator, from an application to the skin of a thick ointment composed of wax, olive and eucalyptus oil and carbolic acid. This smeared over the parts forms a coating sufficiently thick, at the temperature of the skin, to prevent the contact of air with the punctures. In regard to the operation itself, it should, after the plan of Ricord and Duncan,¹ be subcutaneous, and the ligature of catgut. The ligature should be very fine: No. 1 size only. This for two reasons: because it requires less force to cause complete occlusion of a vessel with a thin than with a thick ligature; and a thick ligature embraces a greater portion of tissue, and therefore causes a greater amount of bruising and destruction. The disadvantages and even the danger, in the case of arteries of using thick catgut, have been pointed out by Mr. Barwell and Mr. French. The ligature should not be in that rigid condition in which it usually is from being kept in carbolic oil, as, after soaking in the fluids of the wound, it becomes softened and elastic and in that condition stretches after tying, which, be it ever so little, is sometimes sufficient to prevent perfect occlusion. To soften the ligatures, they may be soaked in a 5 per cent. solution of carbolic acid before being used. I find that the addition of a small quantity of eucalyptus to the carbolic oil in which they are usually kept makes them soft and elastic. In this condition, as in tying with horsehair, a double turn must often be made in the first knot, to prevent it slackening before the second can be brought to fix it. The vein only, with as little surrounding tissue as possible, should be included in the ligature. Not only is there less tissue bruised or devitalized, but less force is required to produce complete occlusion, just as an artery is more easily controlled by pressure on its bared trunk than over superimposed structures. With this object I employ two needles—a long sharp-pointed one, and a blunt grooved one to act as a director. The sharp needle is first thrust underneath the vein, and its point brought out through the skin on the opposite side. It is then withdrawn a sufficient distance in its track to allow of its point being passed over the

vein between it and the skin. To serve as a guide, the grooved director is now inserted in the puncture of exit from which the needle has just been withdrawn, and the needle, now pushed on, meets the groove of the director and comes out at its former aperture. The subjoined diagram (Fig. 1), shows the lines of puncture, which include the vein, with some surrounding tissue. After these tracks were made, I

Fig. 1.

A B C D E, Track of first puncture under the vein. V, E, Point to which the needle is withdrawn. F D F, Track of puncture over the vein. F, Point at which the groove of the director at A meets the needle to conduct it out at its former channel, F B.

formerly used blunt needles and a director to pass the ligature round the vein and tie it. Latterly I have used a triangular-pointed needle five inches in length, with an eye in the middle and a bulbed extremity. It is thinner in the shaft than at the point, so that the ligature threaded through its centre passes without hindrance along with it into the puncture. The needle, with about eight inches of ligature, is thrust under the skin beneath the vein and brought out on the other side, as just explained. It is pushed on till the ligature appears, one end of which is then withdrawn sufficiently to allow it to be passed over the vein, guided out by the director as described, and pushed on till the other end of the ligature can be pulled through. At this stage of the operation, the position of the vein, the ligature, and the needle is as shown in the annexed diagram (Fig. 2). The ligature now

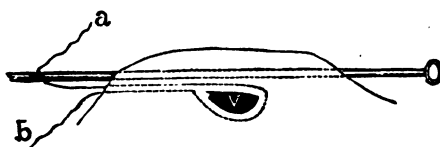

Fig. 2.

b, Ligature drawn through after first transfixion under the vein v. a, Ligature carried over the vein and coming out at the same orifice as b.

forming a loop around the vein is drawn out of the needle, tied in a single knot, and that end of it which was first passed through is drawn back by the needle to the other side of the vein, and the knot passing under the skin, is then tightened. To tie again and complete the reef knot, the eye of the needle bearing the ligature must again be pushed through, and the knot tied as in the first instance; the other ligature is brought back in the needle, which may now be entirely withdrawn, and the knot made fast. The ends are now cut off as near to the knot as possible; this is done by pulling gently on the one-half of the ligature, and cutting it off close to the skin, so that it at once disappears beneath it when divided; the other end is similarly dealt with. The vein is now tied with a reef knot, which with both of its ends is beneath the skin. In this proceeding it will be observed that till the completion of the operation the needle is never withdrawn entirely out of the wound; and that it is by means of the eye carrying the ligature from one side to the other that the knot can be correctly and securely tied subcutaneously. To

¹ Duncan, British Medical Journal, July, 1881.

ensure more complete and permanent adhesion, as well as to avert clotting in the vein, two ligatures must be applied, at intervals not exceeding an inch. The lower ligature to be first applied, and before tying the knot of the upper one all the blood in that part of the vein between the two points of occlusion must be pressed out, so that the sides of the vessel are brought into the closest contact. By this means a much firmer adhesion is obtained than through clotting and subsequent contraction and occlusion. Broca⁴ lays great stress upon the different results of stability of obliteration of veins, produced by coagula and by adhesions of walls. The latter mode of adhesion he asserts to be more solid even than that which takes place between pleuræ; whereas the other is frequently but temporary. The formation of thrombus is to be prevented, in the first place, as urgently pointed out by Erichsen, by keeping the ligature out of the vein; when from the pressure of hæmorrhage, of which there should not be any, there is reason to suppose the vessel is pierced, operation on that spot must be at once stopped, and another chosen. In the second place, by firm pressure on the limb, previous to any ligaturing, by means of a rubber bandage applied from the foot up to that part immediately below the spot chosen for operation. By doing this the veins are emptied of their contents, so that no thrombus with secondary phlebitis can result. For the same reason the bandage is also to be continued over and above the ligatured portions as the operation proceeds. The application to each of the punctures of a small piece of lint moistened with carbolic oil and covered by absorbent carbolized wool completes the procedure. Unless there is much pain, the dressing need not be removed for three or four days. During this time the patient is to be kept in bed; on the fifth or six day, according to the amount of tenderness, the leg may be put to the ground. It is seldom that I have seen suppuration except when thick ligatures have been used or when a large portion of tissue has been included. It has never, in any case, amounted to more than two or three drops of pus, which, after making its way out of the punctures, was immediately followed by healing. As I remarked, the application of two ligatures, less than an inch apart, is the surest means to produce obliteration; in ordinary cases two, or at most three, such obliterations are sufficient to relieve ordinary varicosity. In eighteen cases of operation where the measures and precautions I have enumerated have been observed, I have seen no bad results, or, indeed, any that caused the slightest anxiety. In one instance, that of a person about fifty-five years of age, in whom the saphena was tied six inches above the knee, an acute attack of gout developed, affecting the great toe of the limb operated upon. So far as I am able to judge during two years I have adopted these methods, the results have been permanent upon the vessels ligatured. The most satisfactory cases of all, probably because the disease in the veins was in an early stage of development, were those of some young military cadets upon whom I operated. The varicosities before operation were such as would have disqualified these gentlemen for the service.

In long-standing cases where there is much œdema and great tortuosity of vessels, there are considerable difficulties to encounter. In regard to these, Mr. Duncan's paper, already referred to, gives some valuable suggestions; amongst others, to facilitate the application of the ligature, he advises that a tight rubber band be placed high up round the limb; this, while it brings the veins out in strong relief, has the additional advantage of

rapidly and surely showing by hæmorrhage whenever they are wounded. He has also found that a rubber bandage well applied and kept on for some time reduces that solid brawny œdema so frequently met with in varicose disease, in which the vessels run like gutters beneath the skin and render deligation difficult.

In conclusion, I need hardly observe that the method and precautionary procedures here set forth lay no claim to originality. The method, indeed, is synthetical, composed of elements selected from such procedures of others as promise the greatest immunity from the peculiar dangers which are understood to attend operations on venous tissues. Its details may appear complicated and superfluous; but with the facts of the later investigations of surgical pathologists before us, and the knowledge of how completely in the instance under consideration the results are dependent upon healthy inflammatory action, distinguished from that due to septic causes, there is an enhanced disposition to sacrifice expedition in method to correctness in principle, and to stoop to what may appear tedious minutæ to ensure safety.

Hounslow.

ON THE ACTION OF THE SALTS OF SODIUM, AMMONIUM AND POTASSIUM.

By SIDNEY RINGER, M.D.,

and HARRINGTON SAINSBURY, M.D.

THE difficulties attending the observation of the action of drugs clinically result obviously from the complexity of the phenomena presented; in like manner, the pharmacologist, as long as his investigations relate to the animal organism in its entirety, has essentially to deal with the complex. Inference under these circumstances is correspondingly difficult. If to avoid this source of error our observations be restricted to a portion of the organism, it is clear that our inferences gain in exactitude in exact proportion to the simplification effected. The difficulty now lies in the applicability of inferences so gained when we pass to conditions no longer simple. It was with this difficulty clearly in view that the experiments, the results of which will now be shortly discussed, were undertaken.

The ventricle of the frog's heart was the test tissue selected. Through such ventricle of a heart isolated from the body an artificial circulation was maintained, whilst by means of a suitable apparatus (Roy's tonometer) the contractions were registered on a revolving blackened cylinder. The particular drug used was added to the circulating fluid. We were thus able to compare the working of the drugged and undrugged ventricle under conditions, artificial it is true, but definite and under control.

The structure and function of the tissue so selected are essentially twofold: ganglionic structures and muscular fibres on the one side; rhythmic contractility on the other—i. e., rhythm and contractility. The nervous nature of rhythm may be debatable; but that contractility is muscular is certain.

On such rhythmically contracting heart the action of the salts of potassium, sodium, and ammonium is briefly as follows:

All three arrest the ventricle in diastole; they contrast, however, in the mode of arrest. Thus, as to their action on rhythm: Potassium salts tend markedly to arrest or suspend the spontaneous contractions, whilst yet the heart may be proved to be contractile by suitable excitation. Ammonium salts show no such tendency; the heart

⁴ Gazette Hebdomadaire, No. 16, 1862.

beats, often with an increased frequency, up to the very end—i. e., as long as contractility persists. Sodium salts fit in between, but come very much nearer ammonium than potassium salts, their action on rhythm being very slight.

As to their action on contractility, we have, on the one hand, potassium and ammonium salts acting with almost equal intensity; on the other hand, a wide gap intervening, sodium salts showing but feeble action.

One other point of contrast may be mentioned; it refers to the effect of continuous faradization. This rapidly loses its power to excite the ventricle to contraction when a potassium salt is used; not so for the other bases, and the very slight and somewhat inconstant effect for ammonium and sodium salts contrasts strongly with the uniform and marked effect of potassium salts.

Restricting ourselves to these broad lines¹ of contrast, some important points come out:

First, an important fact—namely, that throughout the salts of potassium, sodium, ammonium, the potassium, sodium, and ammonium elements are traceable. Indeed, in these experiments they appeared to rule the effect. Quite recently,² in a leading article, reference is made to experiments on unstripped muscular tissue by Nothnagel; the same result was observed here, the potassium and sodium action appearing to be independent of the combination of these bases. These experiments, then, on isolated tissues would be confirmatory of the older statement by Guttmann with reference to potassium salts—namely, that they are all exactly alike in the character and intensity of their action.³ The results, however, probably represent but a partial truth. The completer statement probably should be that elements and groups of elements retain more or less of their individuality throughout their combinations, and this would surely apply to either side of a salt—the base and the acid. The value of such statement would be as a help towards classification.

Next, that under these simple conditions specified, a certain relation between potassium, sodium, and ammonium salts is manifest. Potassium standing first as most poisonous and threatening in two directions; ammonium coming next, its action being restricted to destruction of contractility; sodium coming last and ranking as but very slightly poisonous comparatively with either. These experiments, indeed, would make potassium salts some fourteen or fifteen times as poisonous as sodium salts. Is the conclusion not warranted that in their action on the muscular tissue of the ventricle, and on its intrinsic nervous apparatus, these salts will maintain a *like* relation, even though the conditions be the more complex and indefinite ones of the organism in its entirety? It is not that one would exclude action on the nerve centres, vagus, etc., from the effect witnessed on the entire organism, but that one would specify one from among the many factors in the equation. This relation of the salts of potassium, sodium, and ammonium has however been tested on other tissues, and found to hold—e.g., on the nervous system⁴. The results also with the entire organism show that whilst potassium salts are very poisonous, sodium salts can scarcely be made to kill.

Insistence has already been made in various

quarters on the use of sodium and ammonium salts in preference to potassium salts; more especially has this been urged for the bromides.⁵ (The bromide of sodium has been rather largely used in America.) Clinical evidence must obviously give the final judgment; but have we not here clear indication as to the lines on which clinical investigation should be pursued?—the suggestion being that salts of sodium should throughout be substituted for those of potassium and ammonium, till clinical evidence decide that the action of one or other of these bases is required in the particular case under treatment? This suggestion, then, is based not only on the results of experiments with the entire organism, but also on these more definite results gained from experiments on isolated tissues.

It may be added that both at the Children's Hospital, Great Ormond-street, through the kindness of Dr. Barlow, and at the Western General Dispensary, Marylebone, we have had the opportunity of trying the chlorate of sodium⁶ in cases of stomatitis, with ulceration along the edges of the gums, but few cases up to the present have been collected. So far, however, the evidence in its favor is every bit as unequivocal as it is for potassium chlorate, which might be said to be one of the show drugs in therapeutics. Two of the cases gave the best kind of evidence obtainable; they were, namely, cases of relapse, and were cured by pushing the drug.

NOTE ON THE CLINICAL CHARACTERS OF TUBERCLE IN BONE.

By WM. SCOVELL SAVORY, F.R.S.,

Surgeon to St. Bartholomew's Hospital.

It is curious on reflection to see how many striking points of analogy there are between the progress and effects of tubercle in lung and in bone. In the first place the cancellous texture of bone, which is the seat of tubercle, resembles broadly in physical characters the parenchyma of lung. A section of cancellous bone and a section of dried lung have to the naked eye a very general resemblance. The structure of both is aptly described as sponge-like, and this resemblance is drawn more closely when a mass of yellow tubercle occupies the substance of each. In both cases the spongy texture appears to be filled up and rendered solid by the infiltration of the caseous deposit. Then, too, the resemblance further appears in the halo of inflammation or increased vascularity of varying width which so often surrounds the mass. Still further is the likeness shown in the mode in which the tubercle degenerates. The included tissue is broken down and destroyed until, either by the escape or disappearance of the tubercle, a cavity is left in the cancellous bone corresponding very remarkably to a vomica in the lung. Furthermore, the likeness is extended by the relation of cancellous bone to a neighboring joint, and the relation of lung substance to the pleura. Just as pleurisy is so often set up by the disturbance of tubercle in the lung, so synovitis is often provoked by the disturbance of tubercle in adjacent bone; and just as empyema is sometimes produced by the perforation of the lung-wall and the escape of matter into the pleural cavity, so suppuration in a joint, which is too often destruc-

⁶ Through the kindness of Mr. Martindale we were provided with a pure specimen of this salt.

tive, is due to the perforation of the articular wall of bone and the escape of matter into the synovial cavity. In either case urgent symptoms are apt to supervene suddenly on comparatively latent mischief.

Then, I think, the variable progress and effect of tubercle in the lung are oftentimes repeated with singular resemblance in bone. This first struck me many years ago in studying the graphic picture which Dr. Latham drew of the various forms of phthisis in his masterly Lectures on Clinical Medicine, which, by the way, have been happily reproduced by the Sydenham Society under the editorship of Dr. Martin. Just as in lung, so in bone; the history of tubercle is sometimes that of a single formation, which passes steadily, with more or less rapidity, to destruction; sometimes that of several smaller ones simultaneously; sometimes, though this more rarely, that of a number of successive formations which pass through their stages one after another, leading in this way to a gradually extending destruction of osseous tissue. So, again, and in this I think the resemblance is most marked of all, there are in tubercle in bone phenomena very exactly corresponding to what Dr. Latham in the lung, and in the cervical glands as a more obvious illustration, has described as cases of mixed and unmixed phthisis. In one class, during the changes which tubercle, after its formation, is prone to undergo, there is only what may be called a necessary amount of inflammation excited in the surrounding texture; such as is just sufficient to accomplish the result of softening and expulsion, and which subsides as soon as that is effected. This Dr. Latham called the specific limit of the disease. In another class the inflammation provoked spreads widely and deeply beyond this, and becomes much more severe and extensive than is needful for the mere elimination of the tuberculous matter. In short, Dr. Latham's sketch might have been drawn from a study of tubercle in the head of the femur or tibia or in the tarsus or vertebrae.

Within the whole range of pathology I know no better illustration of the value of extended study, or rather of the great loss from limited views which must come of too special observation. For the study of tubercle, if the difficulty would be adequately grasped, must be carried on not only throughout the whole fields of medicine and of surgery, but here, at all events, there can and ought to be no boundary between them. For the largest purpose, the land to be explored must be common to both.

Brook street, W.

REMARKS ON PROSTATORRHŒA.

By D. CAMPBELL BLACK, M.D., L.R.C.S. Edin., etc.,

Extra-Physician to the Royal Infirmary, Glasgow; Physician to the Glasgow Public Dispensary.

THE normal function of all glands is maintained by a healthy coördination of the three divisions of the nervous system—viz., the motor, the sensory, and the sympathetic. The integrity of such coördination may be disturbed by peripheral or central influences, or by lesions of the intercommunicating apparatus. Bodily waste and repair—the persistence of healthy structure—equally with the normal secretion of all glands, are thus dependent on a healthy nervous system, and it in turn on a healthy blood-supply. If at any of the points indicated the normal influence of the nervous system be perverted, the due circulation of blood is interfered with, and in glands one or other of

the following changes take place, as certain conditions predominate.

On the Basement Structure of Glands.

On the Secretion of Glands.

Neoplasm.	Degeneration.	Augmented or diminished secretion.	Changes in the composition of the granular secretion.

The functions of the sexual and urinary organs may be said to be compound in respect that they are partly voluntary and partly involuntary, and that some are participated in by purely cerebral influences, while others are exclusively reflex phenomena in association with given centres of the spinal cord, and thus totally independent of the higher nervous centres. To the former belong the functions of micturition, and to some extent the special sexual functions; while to the latter are to be assigned those of the testicle, the prostate, Cowper's and the other smaller subordinate glands. The nerve centre for the sexual organs is situated in the lumbar enlargement of the spinal cord, and presuming the integrity of the centre and reflex loop, the sexual secretory functions, while they may be influenced by psychical impressions, are carried on quite independently, as all vegetative functions are. In the light of the above propositions we have seen that these functions may be deranged by peripheral, central, or intermediate influences. Under the first category are recognizable the phenomena attendant on the presence of stone in the bladder, hæmorrhoids, preputial irritation, contracted meatus, prostatitis, and varicocele; under the second two categories the phenomena arising from disease or injury to the spinal cord, and the disturbed motor conditions thereby occasioned. These, it will be obvious, comprise retention and incontinence of urine, reflex pain, a peculiar form of spinal paralysis, excessive secretion of the testicle and consequent spermorrhagia, excessive secretion of the prostate (prostatorrhœa), etc.

When several glands discharge their peculiar secretion into a common emunctory it is often difficult to distinguish how far discharges from such emunctory are simple or compound, or to what extent they are the latter. This is notably the case with the urethra, as the term gonorrhœa sufficiently demonstrates. Empirics are never slow to find out the hidden or neglected arcana of medicine and surgery, and profit thereby at the expense of the credulity or unfounded fears of their victims, backed up as they have been in the case of urethral discharges, other than gonorrhœa, by the sensational and ill-advised writings of such men as Lallemand and his followers. The frequency of urethral discharges, at stool especially, and at other times in rarer cases, did not fail to excite their notice, and they forthwith sought, and too often sought successfully, to associate such discharges with the "chamber of horrors" in which Lallemand and such as thought with him, delighted to revel, to the irreparable injury, bodily and mental, it may safely be asserted of countless thousands. As there is no system or form of quackery which does not depend for its maintenance on the kernel of truth within, the expediency of disentangling the true from the meretricious in the present instance is now sufficiently recognized, though there are still considerable differences of opinion among authorities on certain points, to one or two of which it is my present object to direct attention, record my experience, and invite discussion on the part of others whose opportunities of observation are of a more extensive nature than my own. The subject of involuntary emissions of semen is coexistent with the

literature of medicine,¹ but comparatively little pathological significance was accorded to them until the ill-advised and hastily-generalized treatise of Lallemand appeared at Montpellier. Antecedent to this time happy ignorance prevailed upon the subject, and people consequently enjoyed physical and mental health. It was not until 1860, I believe, that a special discharge from the prostate gland was described by Professor Gross;² and in his admirable work on this and allied subjects Dr. Samuel W. Gross defines prostaticorrhoea as an "excessive secretion of a clear viscous fluid, dependent upon chronic catarrhal inflammation of the tubular glands of the prostate. It is included by some authors in their description of chronic prostatitis; but it is an entirely independent disease, as it does not follow an attack of acute inflammation, nor is it attended with suppuration or other morbid changes of the parenchyma of the organ." Erichsen states that "the disease is characterized by the discharge of a few drops of ropy viscid mucus from the urethra after micturition and defecation. It is chiefly of importance from its liability to be confounded with spermatorrhoea, and from the depressing effect consequently produced on the patient's mind," and he further indicates that its diagnosis is to be effected by microscopic examination of the nature of the discharge, thereby indicating that if the discharge contain spermatozoa, the disease is *spermatorrhoea*; if they are absent, that it is *prostaticorrhoea*. Professor Humphrey, in treating of spermatorrhoea, remarks, "Accompanying this malady, or independent of it, there is sometimes a discharge from the urethra of a tenacious fluid, like white of egg, in small quantity, following the urine, or expelled during the evacuation of the faeces, especially when straining is required for this purpose. This symptom causes great alarm to the patient, as he believes that he is suffering from a continued escape of the semen. Such is, however, not the case. I never found any spermatic elements in it. It proceeds apparently from the prostate gland; and its presence in sufficient quantity to issue from the urethra is an indication of a relaxed condition of the ducts of the gland, permitting the secretion to be expressed during the voiding of the urine or faeces." Dr. King Chambers seems to be of a similar opinion, regarding this discharge as one of pure mucus, which may go on for years without any physical or mental impairment unless the patient's mind is directed to the subject. Mr. Teevan, on the other hand, regards this as "true spermatorrhoea," and curiously enough ascribes it to indigestion. Mr. Benjamin Phillips remarks, "At one time I doubted whether this fluid was spermatic, it is usually so smooth, transparent, and homogeneous; but if it be examined under the microscope, spermatozoa can usually (italics writer's) be observed in it. Its thin character has induced people to think that it was a depraved secretion become watery by exhaustion of the secretory organ; and sometimes it may be so, for if a person who complains of the constant escape of the thinner fluid has an ejaculation, the fluid will be thick and grumous. It is therefore most probable that the more fluid portion of the secretion which fills the seminal vesicles is most easily pressed out; and this is a reasonable explanation of this feature of seminal discharges." Considerable diversity of opinion, it is therefore obvious, exists as to the nature of this discharge, the presence of

seminal elements being denied on the one hand and affirmed on the other. Some years ago, in writing on this subject,³ I expressed the conviction that while in the majority of instances the secretion was entirely from the prostate, yet that facts were wanting to prove that involuntary seminal emission did not so occur, and, indeed, that my experience proved the contrary. Further observation entirely confirms me in this opinion. It seems to me immaterial whether the discharge be called prostaticorrhoea or spermatorrhoea (and if the presence or absence of spermatozoa is to regulate the nomenclature, the microscope will at once determine this), the main question being, whether this is a normal condition, whether it is injurious to health, its causes, and how to remedy it. I do not think it will be maintained that this is a normal condition; neither will it, I suppose, be denied that a constant drain of seminal fluid from the urethra is likely prejudicially to affect the health. In the following cases of prostaticorrhoea two groups are recognizable; in the one spermatozoa existed in the discharge, in the other these elements were absent; while the apparent causes were various, and bore out the propositions enunciated at the outset of these remarks.

Case 1 came under my notice in October, 1880. I have but few notes of this case, being that of a third-year's student of medicine. Patient complained of a frequent discharge of tenacious matter from the urethra during defecation. He felt confident that his health suffered, and he desired my opinion as to the nature of the discharge. Examination of the urethra revealed a certain amount of prostatic tenderness, and the microscope the abundant presence of spermatozoa in the discharge as represented in the subjoined diagram.

Fig. 1.

I advised the passing of a full-sized metallic instrument twice a week, and tonic treatment, requesting that I should be informed if the result were not satisfactory. Not having seen the patient subsequently, nor having heard from him, I infer that his ailment disappeared.

In Case 2, given in the patient's own words, those of a highly intelligent gentleman, there were no spermatozoa in the discharge. The cause in this case seemed an aggravated varicocele, a condition which appeared to operate in a twofold manner, the one mechanical, the other physiological. In the former, the veins being large and valveless, a remota is induced in the sexual apparatus—a condition of chronic passive congestion and irritation; in the latter pressure on the spermatic nerves causes

¹ I am not forgetful of the fact that Hippocrates describes spermatorrhoea and tabes dorsalis as arising from venereal excesses.

Περὶ τῶν ἐντὸς παθῶν and περὶ νοσῶν.

³ On the Functional Diseases of the Urinary and Reproductive Organs. Second edition. J. & A. Churchill, London.

peripheral reflex excitability by operating through the centre in the lumbar portion of the spinal cord, and the hypogastric and spermatic plexus of the sympathetic.

W—, aged thirty-four years, consulted me on March 6th, 1882. "Served in India for eleven and a half years continuously; returned on furlough in August of last year; have enjoyed exceedingly good health while there, though serving in most malarious tracts; have hardly felt the effects of malaria, but had a severe attack of cholera in November, 1877, from which, however, I recovered very rapidly. Habits have always been active; can stand more hard work and exposure than most men; have always been in the habit of taking a tolerable amount of liquor, but never to excess. Early in October, 1881, varicocele began to become troublesome, coming on about an hour after rising, and going off about noon. It was accompanied by the discharge of a few drops of gummy fluid after stools and micturition, generally in the latter case, on the first occasion after rising in the morning. This state of things continued until October 15th, when an emission took place. The varicocele then rapidly diminished, and the discharge from the urethra steadily improved. By the middle of November it had almost disappeared. Early in December it reappeared to a considerable extent without the slightest cause. I placed myself under medical treatment, and was told that my liver was out of order! After a little treatment to set this right a preparation of iron was given. The discharge improved, but erections began to give a good deal of trouble at night, and the varicocele reappeared. An emission took place on Dec. 20th, removing the annoyance from the varicocele, and followed, after a few hours, by the almost total disappearance of the discharge. About Dec. 27th the discharge reappeared gradually; also a little varicocele. The latter was entirely removed by an emission on Jan. 2nd. The discharge now began to show itself, usually a considerable time after micturition—three to five minutes. The discharge continued with slight variation up to about Jan. 17th, when it began to disappear. Varicocele became troublesome again about this time, and continued so regularly until Jan. 20th, when it was removed by an emission. Between Jan. 20th and 22nd the discharge was nothing more than a very irregular trace. On Jan. 28th and 29th it increased a little, but decreased again after an emission on the latter night to some extent. Another emission took place on Feb. 5th, followed by a slight increase. I was rather bilious at this time. I stopped the iron mixture, and by medical advice used medicine containing buchu, which appeared to have an excellent effect on the discharge, but disagreed with me otherwise. On Feb. 20th and the two following days there was a slight increase in the discharge, but it passed off again. From Feb. 23rd to 26th it was still wanting, but the penis was irritable, with a prickly sensation and a great tendency to erection. The irritation continued next day and the following one, on which the discharge reappeared at stool. On March 2nd the discharge assumed a yellowish appearance throughout the day and clear after stools. On March 3rd the yellow discharge before mentioned had given place to the usual one afterwards. The excessive tendency to erections at night has continued since about Dec. 15th. I think that the penis is in a state of erection more or less during the whole of my sleep. I have repeatedly to get up and thoroughly wake myself to get rid of it."

Such is the patient's own succinct and intelligent account of his condition. I saw him on March 6th of the present year. I found the left testicle

greatly reduced, and the attendant veins large and tortuous. A good deal of genital irritation was complained of, and the urethral discharge was considerable. I had no hesitation in recognizing, as cause and effect, the genital irritation, the discharge at stool (prostatorrhoea), and, doubtless, the involuntary emissions during sleep to some extent. It is particularly noteworthy that seminal emission was followed invariably by a diminution of the varicocele and of the urethral discharge; and, under all the circumstances, I felt justified in recommending an operation for the radical cure of the varicocele, administering at the same time the bromides of camphor and iron, which quickly diminished the troublesome genital irritation complained of. As operative interference had been discountenanced by the patient's London attendant, I requested that he should take further advice, and Dr. Alexander Patterson agreeing with me as to the expediency of the contemplated operation, I had recourse to it on March 17th, adopting the method of occluding the veins by subcutaneous wire loop, which I had previously found to answer well in similar cases. After eighteen days the wires were removed, and the veins operated on seemed permanently obliterated. On April 27th the patient wrote: "I begin to notice a considerable general improvement in its (the testicle's) size and consistence. The discharge has entirely ceased." Subsequent communications were correspondingly encouraging, and I had independent testimony to the efficacy of the operation through the courtesy of Mr. Bryant. On September 13th, 1882, the patient writes: "The varicocele gives no trouble even after prolonged exertion, walking or rowing; and my general health has improved greatly. . . . The left testicle has not increased much in size since I last wrote to you, but has grown much firmer. I should say its cubical capacity must be three or four times greater than before the operation. The whole mass, veins and testicle, is about the size of the other testicle now."

CASE 3 differs entirely from the foregoing, the cause being, I believe, injury to the spinal cord at a comparatively remote period. Besides, the discharge from the urethra contained spermatozoa and prostatic tube casts.¹ (Fig. 3.)

J. M—, aged thirty-two, consulted me on Nov. 2nd, 1881. There was no history of masturbation; he very moderately indulged in sexual intercourse. Twelve years ago he had gonorrhoea, which lasted a few months. About this time the patient fell into a ship's hold, alighting on his back on a prominent object, and also upon the occiput. He remained unconscious for about half an hour, and his spine was considerably affected. Subsequent to this period, particularly after lying on his back, on awakening, the patient noticed that his linen bore the marks of seminal emission. Emissions occurred unconsciously to the extent of twice or thrice a week. Simultaneously, and down to the present time, since receipt of the injury, more or less slimy, tenacious matter escaped from the urethra at stool. Six years before this the left testicle was injured by the falling of a box upon it. Inflammation and much swelling ensued, which, however, ultimately entirely disappeared. The slightest excitement, such as travelling on an omnibus, etc., causes irritation of the injured testicle. The parts are quite normal. No spermatozoa were found in the specimen of slimy matter passed from the urethra on first examination; but on Feb. 2nd abundant spermatozoa were found, as represented in Figs. 2 and 3 subjoined. On passing an instru-

¹ Compare with Mr. Solly's case of Spermatorrhoea from Spinal injury, page 101, "On the Functional Diseases of the Urinary and Reproductive Organs." (Black.)

ment marked tenderness was found to exist in the prostatic region. To have bromide of potassium, combined with tincture of belladonna and buchu. This medicine very much moderated the seminal emissions. A large instrument was passed twice weekly.

April 17th, 1882: Still some discharge from the urethra at stool, but containing few spermatozoa. More or less swelling of the prostate only affording passage to a small instrument. On a subsequent visit I found that the spermatozoa had entirely disappeared, and the amount of discharge was greatly diminished. As I have not seen the patient quite recently, I am unable to say whether he is completely cured, while, in my opinion, his progress towards recovery was such as to warrant the belief that he is. It should have been mentioned that this patient had been under medical treatment for this affection prior to his consulting me, and that he felt positive, as his appearance seemed to indicate, that his bodily vigor was undetermined by the persistence of the discharge.

In Case 4 the history is somewhat different.*

Fig. 2.

W. H.—, aged twenty-nine, consulted me on the 7th October, 1881. Since the age of sixteen until within a few months he had been addicted to the habit of masturbation. Between the years of sixteen and nineteen he severely taxed his sexual system in this manner. His present complaint is that no matter how prolonged sexual intercourse may be there is no seminal emission. There is a slight orgasm and a mere oozing of slimy matter from the urethra. Slimy matter escapes from the urethra at stool, and patient has nocturnal emissions twice or thrice weekly. With the exception of a varicose condition of the right testicle, the sexual organs present externally no peculiarity. An examination of the urethra reveals prostatic hyperæsthesia. As an operation for the varicocele could not be conveniently submitted to, the patient was advised to have a No. 10 metallic catheter passed twice weekly, and to have iron and strychnine, with bromide of iron, and watery extract of ergot internally. The subjoined diagram represents the nature of the urethral discharge.

On February 1st, 1882, the patient writes: "I have followed your advice by using the No. 10 catheter twice weekly, and with the result that the nocturnal emissions have ceased to trouble me; but the emissions at stool are persistent and copious. No matter what the condition of the bowels may be, the emission takes place every time with-

out exception." I have not heard from this patient since, and am thus unable to say what his present condition may be.

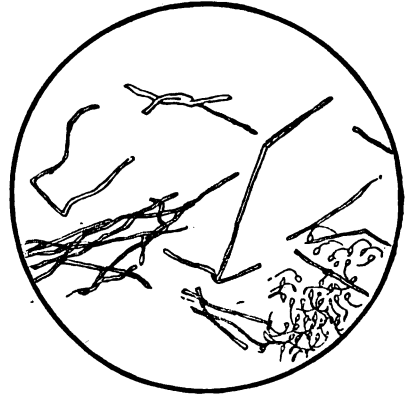

Fig. 3.

Case 5 is typical of a large number of cases of prostaticorrhoæ and sexual debility. August 18th, 1880, a medical student, aged nineteen, consulted me regarding the discharge of glairy matter from the urethra simulating semen, and staining his linen. Three years before he had gonorrhœa, and from that time until within the last year prior to my having seen him he indulged in great sexual excess. Patient used various remedies for his condition, amongst others tincture of steel, with

Fig. 4.

tincture of cantharides, and strong injections of nitrate of silver. The sexual organs presented no abnormality. On passing an instrument the entire urethra was found in a state of intense tenderness, being aggravated in the prostatic region. Thick glairy matter escaped from the urethra at stool, in which, however, the microscope revealed no spermatozoa. Nocturnal emissions happened often, and frequently unconsciously, being discovered in the morning simply by the effect on the linen; and pain was referred to the region of the prostate. Irritation having been subdued by the use of sedatives and bougies, a course of steel completed the recovery.

In the light of my experience of these cases, by no means infrequent, I am disposed to regard prostaticorrhoæ as consisting of two forms, the discharge in the one being characterized by the presence of spermatozoa, while in the other this element is

* Dr. S. W. Gross describes a case very similar to this at p. 125 of his book.

wanting. It is preferable so to regard it, seeing that in other cases diurnal seminal losses, quite independent of straining at stool and micturition, are no doubt attributable to excesses, while others are to be ascribed to idiopathic excitability of the sexual system. Of the latter, an example came under my observation in May, 1879.

H. E.—, aged twenty-six years and a half, never masturbated. The patient describes himself as in capital health, independently of his sexual system. When a lad of from thirteen to fourteen he says, in common with so many boys, he gave way to reading obscene books, and at fifteen had sexual intercourse, from which date seminal emissions began. At the age of eighteen he had emissions on an average once a week. At twenty-six years and a half (present age), emissions take place more than once a week. They occur at night both with and without erections. "If I lie on my left side, I may feel tolerably certain of having an emission, and then without erection." I find from my notes that strychnine and iron, with bromide of camphor, nux vomica, and watery extract of ergot, were prescribed; but there is no note as to the result. The etiology, pathology, and treatment of prostaticorrhœa, as I regard them, are embodied in the foregoing observations. A few words of special amplification may not be out of place. Speaking generally, prostaticorrhœa may be excited by any condition determining vascular plethora of the pelvic viscera. I do not think that it is invariably preceded by acute inflammation of the prostatic urethra as maintained by Dr. S. W. Gross, for I am persuaded that it may be due to passive congestion of the prostate and adjacent organs. I do not think that sufficient prominence is given to a contracted meatus, congenital or traumatic as a cause of prostatic and orchitic congestion. I have divided the meatus, in such cases, with the best results.

Therapeutics is the most vulnerable department of medical science. It may truly be regarded as the sanctuary of superficial reputations. As few thinking men attach much importance to by far the greater portion of what is recorded as to the alleged efficacy and influence of drugs—most of it begotten of incompetent observation—I record with diffidence my opinions as to the influence of remedial agents in the conditions under consideration. In chronic urethral and prostatic hyperæsthesia few means operate more beneficially than the passing of a full-sized metallic instrument into the bladder; the frequency with which this is to be performed should be inversely to the amount of irritation. As the ultimate facts of therapeutics are so few, I am of those who think that such as have been handed down to us ought to be cherished, and that the chimerical pursuit of new ones in connection with new remedies is not unadvisedly to be encouraged. That bromide of potassium exercises a sedative influence over the motor sexual and urinary centre in the spinal cord is admitted to be one of the ultimate facts of therapeutics; nay in some cases so marked is this influence that when the drug is taken in large doses a temporary retention of urine is thereby occasioned. It is a modification of this toxic influence that we desiderate in bromide of potassium as a therapeutic agent. It is extremely probable that this impression extends along the whole anterior portion of the spinal cord. Reflex action is thus inhibited, and muscular excitability diminished. It seems to me that the sympathetic and the motor systems may be regarded as two opposite poles on whose properly balanced tone normal function, especially circulation, depends. Hence impressions on the sympathetic (fibres of Remak) which diminish its inhibitory power, exalt motor influence, and thus

accelerate the circulation and determine congestions. If on the other hand motor influence is diminished, sympathetic dominance is correspondingly established. Bromide of potassium undoubtedly possesses the latter property. Thus it induces sleep by causing cerebral anæmia; and, by a similar influence on the pelvic viscera, operates beneficially in all cases of uro-genital hyperæsthesia and congestions. The bromides of camphor and iron seem to possess similar properties. Belladonna, and its active principle atropia, act apparently as therapeutic agents by stimulating the fibres of Remak, and are thus of acknowledged efficacy in the treatment of enuresis and spermatorrhœa; and atropia, according to Rosenthal, and Dr. S. W. Gross, in prostatic discharges. When there is reason to suppose that there is an atonic condition of the prostatic ducts, such motor stimulants as strychnine and ergot of rye are specially indicated.

PERFORATING ULCER OF THE FOOT AND PROGRESSIVE LOCOMOTOR ATAXIA.

By FREDERICK TREVES, F.R.C.S.

Assistant-Surgeon to, and Senior Demonstrator of Anatomy at, the London Hospital.

PROF. BALL and M. THIBERGE, in a paper read before the recent International Medical Congress,¹ have endeavored to show that there is a "direct connection" between perforating ulcer of the foot and locomotor ataxia, and bring forward twelve cases to demonstrate that circumstance. They assert that the foot sore has a twofold association with the spinal ailment. It may be one of the earlier or premonitory symptoms of the cord disease, or, on the other hand, it may prove one of the late or terminal manifestations. Before remarking upon these important conclusions I may detail a case now under my care in the London Hospital that would appear to bear out the assertions just made.

The patient is a single woman, a cook, aged thirty-nine. There is nothing important to note in either her family or personal history. Five years ago she developed a suppurating bunion over the left great toe. In about eighteen months this healed, and gave no further trouble. Shortly after it healed—i. e., about three and a half years ago—a perforating ulcer appeared over the head of the metatarsal bone of the second toe. This was preceded by a painful corn, under which an abscess formed. The ulcer is said to have led down to bare bone. Under treatment at the Infirmary at Eastbourne the sore healed, but soon broke out again. It healed and reopened several times, and became at last so troublesome that the left foot was amputated (Chopart) at the Eastbourne Infirmary some eight months ago. After the healing of the stump, which is firm and substantial, she returned to her work, and her feet remained sound until six weeks ago. At this time she developed a perforating ulcer over the head of the metatarsal bone of the second toe of the right foot. It was preceded by a corn and an abscess, as was the sore on the left foot. Shortly after this a like ulcer appeared on the most prominent part of the stump of the left limb, appearing in like manner after a dense corn, beneath which suppuration had taken place.

She has now a circular callous ulcer surrounded by horny epidermis on both the right foot and the stump of the left foot in the situations indicated. The former leads to bare bone, the latter to a sinus three-quarters of an inch in depth. Seven

¹ Transactions, vol. ii., p. 52. London. 1881.

weeks ago she began to stagger in her gait, and has since then fallen down several times when walking. She is now remarkably ataxic in her lower limbs, the upper extremities being sound in that respect. She cannot walk without assistance, nor can she stand when the eyes are shut. There is anæsthesia of both lower extremities, which is somewhat unequally distributed as to degree. There is absolute absence of tendon reflex in both limbs. The feet do not sweat in excess, nor has that feature at any time been observed. The pupils act during accommodation, but are absolutely inactive to light. Her vision is normal. She has no strabismus, and there is nothing especial to note in her fundus. She has had "lightning pains," but no gastric disturbances, no neuralgia, and no trouble with her sphincters. It will thus be seen that the original ulcer of the left foot made its appearance before any evidences of ataxia had developed, and if one could accept without reservation MM. Ball and Thibierge's assertions as to the relation of this ulcer to locomotor ataxia, it will be obvious that the sore assumes a very remarkable importance in general medicine. Unfortunately MM. Ball and Thibierge's statements are not made without reservations. They are forced to recognize more than one form of perforating ulcer of the foot, and of the possible varieties they only assert that one form has part with the spinal malady. Their general conclusion as to the nature of the sore is that it is "a trophical disease of nervous origin," a conclusion closely in accord with that expressed by Messrs. Savory and Butlin in their admirable monograph,* wherein they assert that "the so-called ulcer is the result of pressure or violence to structures whose nutrition is impaired or whose vitality is defective from disease or degeneration of the supplying nerves." Now the many contributions that have of late years been made to the pathology of this foot affection would tend to claim for it the dignity of a special disease, and give to it a very pronounced clinical individuality. Thus the French authors above mentioned would place one form of the foot sore among the specific manifestations of locomotor ataxia, and from their paper one would gather that they consider its relation to the cord disease as close and as pronounced as are the relations of the affection known as Charcot's joint disease. Messrs. Savory and Butlin moreover, in the monograph referred to, are disposed to give the following clinical picture of perforating ulcer: It is an affection more common in men; it attacks certain parts of the sole; it is commonly symmetrical; it is particularly associated with a certain amount of anæsthesia of the part, with sweatings of the foot and with certain peripheral nerve-changes. That foot sores are met with these characteristics no one would dispute, but the grouping of these various characters so as to form one special disease may, I think, be a matter open to question. I have had under my care during the last few years three men with ulcers situate on the soles of the feet, that were symmetrical, that were preceded by suppuration beneath a corn, that led down to bare bone, and that long resisted treatment. In no one of these cases was there any anæsthesia of the part, nor any undue sweatings of the foot, nor any evidence of nerve affection of any kind. One man has been under observation at various times for two years, and is still free from any obvious trace of nerve disease, either central or peripheral. In these three individuals I imagine that the disease is solely and purely local—as purely local as a bed sore under the heel of a man confined to bed

with a fractured femur. A corn forms; it presses like a foreign body upon the soft parts beneath; that pressure leads to suppuration; the pus moves deeply on towards the parts offering the least resistance, and by the time it has found its way through the dense corn-tissue, it has probably in the other direction reached the bone. That any lesion of the nerves of the extremity would favor the development of such a local sore is obvious; just as a bed sore would be more likely to occur in a subject of paraplegia than in a patient bedridden with some other than a disease involving gross nerve change. In one of Messrs. Savory and Butlin's cases the patient appears to have suffered from some infantile affection of the nerves of the limb, and yet from a perusal of the paper one gathers that the symptoms of that nerve affection are included among the individual features of the sore that in time he developed upon his sole. I imagine that it would be more correct to ascribe the anæsthesia, the sweatings, and the microscopic changes in the nerve-trunks, to a central or peripheral nerve disease in relation to which the foot sore is a mere coincidence. To make use of these characters to complete the clinical individuality of the ulcer appears to be on a par with a description of a bed sore in paraplegia, as a sloughing ulcer associated with loss of power in the lower extremity, with anæsthesia, with certain visceral troubles, and with certain gross changes in the cord; all these features being maintained to be essential to the clinical individuality of the sore.

I would urge, therefore, that this "perforating ulcer" is a purely local affection, produced by purely local causes, which causes would act with increased vigor upon a part whose vitality is in any way impaired, but that that impairment is not of necessity dependent upon disease or degeneration of the supplying nerves. The relation of the malady, therefore, to locomotor ataxia would appear to be quite casual and unimportant, and of no more clinical value than would be a burn on the sole of an ataxic subject who had unconsciously brought his foot in too close contact with fire.

In conclusion, exception may fairly be taken to the somewhat misleading name applied to this sore, since it does not appear to really perforate the foot in any ordinary case. Indeed the selection of its especial title appears to have been founded upon the same grounds that influenced Bottom in selecting a title for his vision, and of which he is reported to have said, "It shall be called Bottom's Dream, because it hath no bottom."

Gordon square, W. C.

THE UNITY OF SURGICAL PRINCIPLES IN WOUND AND FRACTURE TREATMENT.¹

By SAMPSON GAMGEE, F.R.S. Ed.,

Consulting Surgeon to the Queen's Hospital, Birmingham.

WOUNDS and fractures are alike interruptions of continuity—the former of the soft, the latter of the hard parts. They differ in the density of the tissues involved, and proportionately in the time required for reunion; but they are essentially similar in processes of repair and principles of treatment. In wounds and fractures, division of tissue is the essential fact which gives rise to a common chain of events—mobility, disordered innervation, and effusion,—which become causes of ulterior pathological results, if their development be not checked by proper treatment. The indication,

* Transactions of the Medical and Chirurgical Society, vol. xii., 1879, p. 373.

¹ Read before the Medical Society of London, Nov. 6th 1882.

common to the vast majority of wounds and fractures, is to bring the severed parts together and keep them so during the process of repair. How that indication shall be fulfilled—what peculiar appliances are demanded by injuries in particular situations, and by such complications as contusion, hæmorrhage, and inflammation—are questions traversing the whole domain of surgery; fit themes for a treatise, only admitting of cursory treatment in a paper for an evening's discussion. It will be my endeavor only to select for comment those salient principles and points of practice on which agreement is most to be desired and nearest of attainment.

Firstly, as to the reduction of fractures of the limbs; that should be immediate, and maintained with the nearest practicable approach to immobility, a rule of practice of which no other in surgery admits of fewer exceptions. In selecting from amongst the numberless contrivances for maintaining immobility, preference should be given to those which admit of accurate moulding to the limb, including the joint above and below the seat of injury. It is beyond question that, with wood and iron splints, many surgeons have for generations achieved excellent results in fracture treatment; but, for comfort to the patient and freedom from complications, moulds are best; they can be constructed with a great variety of materials—plaster, gum and paraffin, millboard (plain or soaked with dextrine), gutta-percha or poro-plastic felt. The last-named and dextrined millboard are, I think, the most handy and efficient; but, where all are good in principle, choice may well be left to the predilection which grows out of individual experience. Whatever splint or mould be used, let it be well padded, and I know no pads equal to those made with absorbent gauze and cotton, which possess practically indestructible elasticity. The materials of which bandages are made, still more the method of bandaging, are of the first importance. Uniform elastic compression powerfully contributes to preventing muscular contraction, and *pro tanto* securing immobility. It prevents extravasations, and, when they do occur, promotes their absorption. I employ pressure in the treatment of all fractures, with perfect elastic padding, light, yet decidedly compressive, smooth bandaging, without ruck or reverse. It is many years since I used one of the unbleached calico bandages common in most hospitals. Preference should be given to these soft, bleached, absorbent bandages. A depth of two inches is the handiest, the rapid spiral the most convenient, comfortable, and efficient, mode of application. In bandaging a leg, for instance, having previously padded it, a couple of circular turns are made just above the ankle. The roller is then carried along the dorsum of the foot, and a circular turn made around the roots of the toes. With a few figures-of-8 the foot, including the heel, is covered; the roller then carried spirally along the front of the leg to the knee, here made fast with a circular turn. Alternately ascending and descending figures-of-8 complete the elastic investment. The method is applicable, with trifling variations of detail, to all parts of the body. Whenever practicable, suspension will be found of the utmost service as an addition to the means of maintaining immobility. The suspension of a limb in two or more loops of bandage or leather is not what is here meant; that is comparatively fixed elevation, of unquestionable advantage for position, but not a perfect swing; for this a fine cord is even better than a chain. The greater the motility of the suspending medium, the more completely does it oscillate and exhaust any motor power communicated to the limb; in other words, the fragments of a suspended broken limb, once

perfectly adjusted, can be kept at rest in direct proportion to the perfection of the swing.

Another form of suspension, different in principle and mode of application, but still very useful, is that of suspending a weight to a limb. It overcomes muscular contraction by steadily exhausting it, and alone, or in combination with moulds and pressure to an injured part, is of great service in maintaining immobility. Assuming so much conceded for the treatment of a simple fracture, agreement would probably be less complete, if a fracture complicated with swelling, sanguineous or inflammatory, were in question. But in such a case, no less than in the simple one, should reduction be immediate, with elastic compression, absolute immobility, and oscillatory suspension. Digital compression of the main artery will assist in promoting absorption. In a very few hours the outside of the apparatus becomes loose, and its elastic construction admits of fresh padding and compressive bandage, without disturbance of parts, and with unfailing benefit in promoting absorption, checking inflammation, and consolidating repair. The additional complication of a wound or a bleb makes no substantial difference; given a compound fracture, only let the fragments be immediately and accurately adjusted, the wound closed with all necessary provision for perfect drainage, the limb immobilized compressed and swung, and, in the vast majority of cases, the fundamental indication will have been carried out, reducing the compound to a simple fracture, and treating both on identical principles.

If a simple fracture, say of the clavicle because it admits of easy observation, be not at once immobilized, material is thrown out between and around the broken ends of the bone, the deposit thickens, the part becomes hot and painful. Such a condition is best seen in those, happily, rare cases in which a fracture of the clavicle goes for some days undiagnosed. Immobilize the limb and the callus vanishes, all the more rapidly if compressed under an elastic pan. Given a flesh wound in most parts of the body; if the edges be at once accurately brought together, and kept so, provision made for deep and surface drainage, and immobility maintained, direct union takes place, all the more surely if the part be kept in a position to favor venous return and prevent arterial afflux. Here, again, perfectly smooth elastic compression is of the greatest service, not merely in maintaining contact of the deeper, as well as the superficial, lesion, but in restoring the balance between elastic resistance and blood pressure, which is the normal condition of living parts. Let a flesh wound, like the one we have just been considering, not be accurately adjusted; let it be treated with water dressing or a poultice, with the limb dependent and not immobilized. The edges become tumid, the wounded surface discharges and stinks, the surrounding skin is red, tumid and painful. In this state, raise the limb to empty it of its blood, approximate the edges, resort to elastic compression and immobilization, swelling and pain vanish as if by magic, and healing proceeds, just as in the case of the fracture with swelling which we were considering a few minutes ago. A fracture with a wound complicating it, the condition generally known as compound fracture, will be found amenable to treatment on the principles enunciated with the happiest results.

My remarks have hitherto been directed to injuries of the limbs. Their truth and practical value are equally well, if not better, illustrated in injuries of the head, with some modifications rendered necessary by the condition of parts. In fracture of the vault of the cranium without wound, the great indications of rest and prevention of ex

travassation are fulfilled by keeping the patient in comparative darkness, in the horizontal position, with an ice-cap. No wounds do better than scalp wounds under dry dressings, elastic compression, and a minimum of subsequent interference. An adaptation of the same principles, according to the exigencies of particular cases, will ensure success in the treatment of a large proportion of compound fractures of the skull. The question of trephining is one of special and exceptional interest, to which it would be here impossible to do justice. But as I have no wish to shun difficulties, and to restrict the scope of discussion, I may briefly state that there are very few cases in which I consider trephining justifiable in fractures of the skull. I have practiced it, and seen others do it, with happy result; and I can conceive of cases in which I should not only trephine, but be prepared to incise the membranes and the substance of the brain, to fulfil local indications of effusion and compression. But if we go back to the early days of this controversy, and trace it down to our own time, I am clearly of opinion that more people have owed their death, than their life, to the trephine.

To ensure absolute rest in wounds and fractures, immobility should be secured to the utmost practicable extent, while the reparative process is going on; but no longer. Every surgeon knows how much mischief results from rest too long persisted in. The experience only affords another illustration of almost every truth, psychical and physical; carried to extremes it becomes a vice. With this reservation, the practical application of which must depend upon the exigencies of particular cases, immobility is one of the most powerful factors in surgical therapeutics. A corollary of that proposition is infrequent dressing. On this point the agreement of surgeons at home and abroad has grown very manifestly during the last few years. Whatever the nature of the injury, it is scarcely possible to be too accurate and complete in first dressings. Then watch the thermometer and the pulse, the patient's expression and the state of the skin; and so long as those cardinal indications point to safety dress as infrequently as possible. To this end absorbent dressings contribute materially, and if they be not sufficient to ensure perfect drainage, one or more tubes may be employed for the purpose. By keeping them long, and carrying them out through the pads, it is easy to collect the discharge in a pad lightly placed over the end of the tube, so as to combine frequent removal of discharges with immobility of the apparatus.

Experience proves that the more absolute the immobility, the more evenly the limb is compressed, the closer attention is paid to position, proportionately less are irritation, vascular turbulence, and consequent effusion. The healing part shrinks as it consolidates, and dries in direct proportion as its nervous and vascular life is controlled. "That under dry and infrequent dressings, absolute rest, physiological position, and elastic pressure, most wounds and fractures heal," is a proposition which I have striven to defend since I formulated it years ago. The argument so far has been in the same direction, and that because experience only confirms its soundness.

Generalizations are proverbially difficult in a science and practice like that of surgery. However sound be their foundation, however close the reasonings by which they are arrived at, their success in particular cases depends on the judgment, skill, and care with which they are applied. To the reservations already made I must add something on "dry dressing," which, unqualified, is a very misleading designation of this plan of treatment. It is certainly entitled to be called "dry

dressing," inasmuch as water is not used, and even astringent or anti-putrescent lotions very sparingly so; but success demands attention to all the essentials of the physiological treatment of surgical injuries—immobility, position, and pressure, drainage and infrequent dressing, pure and non-putrescent materials; gentle, patient, and skilled manipulation; intelligent and unceasing watchfulness of constitutional states.

Fresh wounds without loss of substance are particularly suited for the plan of treatment here recommended. They should be put up without water, the edges accurately in contact; always bearing in mind the necessity of providing for drainage outwards of any effused fluid. Under absorbent pads and elastic pressure, with absolute rest and attention to position, the vast majority of fresh wounds heal rapidly, solidly, and painlessly. When the dressing is changed, which it should only be infrequently, no water should be employed; but if there be any discharge and necessity for cleaning, this can best be done with a pledget of dry lint or of absorbent gauze and cotton; all manipulations to be of the lightest. Such dry dressing simulates the natural scabbing process, but is really more perfect. Wounds of many inches in length heal so directly and perfectly under dry dressing and elastic pressure, that in the course of a few days it is often difficult to detect the fine linear scar on the dry and shrivelled skin. If a fresh wound be attended with loss of substance, some boroglycerine should be poured on the part before application; it prevents too close adhesiveness, and possible bleeding, when the dressing is removed, and has the further advantage of preventing decomposition.

The necessary employment of sutures and adhesive plasters, according to requirements, need not be dwelt upon, and I shall only briefly remark that instead of, or in addition to, such bonds of union, I frequently employ styptic colloid, compound tincture of benzoin, or collodion.

In wounds with large loss of substance, if healing be slow, action may profitably be stimulated by a variety of the well-known astringent applications in ointment or lotion, than which I do not know a better than the old red lotion,¹ with a liberal addition of glycerine. Position, rest, and pressure remain cardinal indications, poultices and water prohibited. By this I mean stagnant water in the shape of water dressing, which is nearly as potent as a poultice in promoting suppuration and decomposition. It is otherwise with cold-water irrigation, which is consistent with, nay may be made conducive to, perfect drainage, and by its astringent and sedative action produces effects very similar to those of rest and pressure. Cold irrigation is not easy to apply continuously comfortably, and one of its great advantages, the low temperature, may be secured by ice bags.

I hope I have made it clear that while the absence of water is a prominent feature of the dry dressing method, an essential is the maintenance of immovable apposition under elastic pressure, whereby the dynamics of the circulation are so controlled that the part is only allowed blood enough to nourish it. Irritation, the great cause of stasis and effusion, is reduced to a minimum, and the part is maintained in a state the nearest approaching to inaction and dryness. In direct proportion the material and the possibilities of decomposition are averted.

Contused and inflamed wounds likewise afford conclusive evidence of the soundness and general applicability of the principles and methods just

¹ A solution of one or two grains of sulphate of zinc in water, with the addition of some compound tincture of lavender.

related. The dressing which I hold in my hand was removed from one of the *employés* in an iron warehouse. He was moving some pigs of iron, when one, weighing a little over a hundred weight, fell on his right foot. I saw the case very shortly afterwards, and found the foot very much swollen, its bony outline obliterated, the skin bluish and shining, with a star-shaped wound on the centre of the instep. Having satisfied myself that no foreign body was present, I dried the wound and placed over the dorsum of the foot this fold of lint, well soaked with compound tincture of benzoin, over it this large pad of absorbent gauze and cotton, and then a compressive bandage from the roots of the toes to the middle of the leg. I enjoined my patient to keep perfectly quiet, lying during the day with his head at the foot of a sofa and the injured foot over its head. I did not remove the dressing until the eighth day, when the wound was healed, the outline of the limb perfect, and though the skin was mottled, as from a bruise, up to the middle of the leg, it was cool and painless.

You see how the blood had penetrated, though in small quantity, through the dressings, and dried on the outside. The tincture of benzoin had acted as a coagulant and antiputrescent, and drying into the lint served the purposes of a mould. Its styptic property was assisted by pressure and position, under which the effusion was absorbed; the part shrank, and the wound healed without any further interference. This result, a typical one of the method, was not a simple consequence of a dry application, but due to a variety of causes which combined in controlling the circulation and promoting reparative action in accordance with demonstrably true principles of animal physics.

A punctured and inflamed wound of a much more serious kind, but with equally happy issue, calls for a few words. I was asked to see a licensed victualler who a week previously, while carving a joint, had thrust the point of a long knife into the centre of the palm of the left hand. He proceeded at once to a neighboring hospital, where the hæmorrhage was arrested and a carbolic dressing applied. Hæmorrhage recurred the third day, and the padded wooden splint, which I have here, was firmly applied with a calico roller to the hand, and the patient sent home with the request to attend in a few days. The arm swelled, pain was intense, and my attendance was requested. The splint you notice is barely long enough to reach from the tips of the fingers to the wrist—a useless contrivance for purposes of rest, a fulcrum for intolerable pressure under the strong calico roller firmly applied to check the bleeding. I found the palm of the swollen hand full of filth, which I lightly cleaned out with dry lint; blood issued rather freely from the wound, into which I lightly brushed iodized colloid with a camel-hair pencil. I put the man to bed, and raising the limb in the vertical position, padded it and bandaged it, interlacing the spiral turns every now and then with a piece of moistened millboard. I left the man in bed, with the hand well raised, in perfect comfort. He had had no sleep for nights, but was never disturbed afterwards; with four changes of pads in a fortnight swelling rapidly subsided, and healing was perfect without an untoward symptom. Pressure over a short strong splint like this is just the oppressive constriction which cannot be borne, and is a source of incalculable mischief. On the other hand, the equable elastic pressure subsequently employed, with absolute rest and position on sound principles of vital dynamics, conduced to a surgical result in which the dry dressing was merely one factor.

Only the other day I was asked to see this case in consultation. A gentleman had bruised the

front of his leg against the step of his carriage. The part injured was not the shin, as is usual, but the muscles outside it. Cooling lotions had been applied for two or three days; but, swelling and heat increasing, poultices were substituted, and an incision for the evacuation of matter was contemplated when I was called in. I found the part much swollen, red, and tender, and have no doubt that an opening would have given exit to pus. But the patient being very averse to the knife, I consented to endeavor to avert it, while stating clearly that the surgeon was justified in recommending it. With his assistance I raised the limb vertically, padded it and bandaged it over interlacing strips of wet dextrined millboard from the toes to the knee. The patient was ordered to remain in bed with his leg in a swing. In a few hours the bandages and millboard lattice-work were comparatively loose. Every twelve hours an outside bandage was applied with equable pressure, and at the end of forty-eight hours the limb was exposed; we found it pale, cool, shrunken, and painless.

If this may seem to point to a too mechanical doctrine of inflammatory development and treatment, I beg you to recall your experience of the everyday surgery of the upper and lower limbs. How rare are congestions and ulcerations of the former, how common of the latter. Here is a big, boggy, red leg, with a saphena vein nearly as big as an index-finger, and an irregular, dirty red, filthy sore, nearly as large as the palm of the hand, the surface of the limb tense and shining, and often so tender as scarcely to bear being touched with a feather. Put the man on his back, raise the leg vertically by the heel, in one minute by accurate test I have found the circumference at mid-calf diminish exactly one inch. While an assistant supports the heel, strap the leg from the ankle to the knee with perfectly equable pressure, leaving two or three narrow interspaces for drainage opposite the ulcer. Over the plasters covering it, and surrounding the leg, place a good large pad of absorbent gauze and cotton; then bandage spirally and evenly from the toes to the knee with a good compress over the vein. If the patient can rest a day or two with his leg in a swing all the better; but even if he walks about at once, the compressive apparatus soon becomes loose. When it is opened in two or three days the pad is full of discharge, the limb much shrunken and paler; cleanse it with dry lint or absorbent cotton, reapply the same apparatus, change it every fourth or fifth day, and healing progresses in comfort and without a check. Should the sore seem languid at any one of the dressings, it may be beneficially lightly touched with sulphate of copper, or have a zinc and glycerine lotion brushed over it, with a camel-hair pencil. In the main, the state of such a leg is owing originally to disturbed nutrition from interference with the circulation by mechanical causes. So, too, its healing is brought about by restoring that balance of physical conditions, which is essential to the equilibrium of blood-supply, innervation, and healthy nutrition.

On the same principles, and practically by the same method, most cases of so-called erysipelas after injury may be successfully treated. Under wet applications they spread; whereas they rapidly subside under the elastic pressure of dry absorbent gauze and cotton pads and perfect bandaging. Even when the subjacent tissues have become sloughy, and matter has formed, subsidence on the plan indicated is most rapid, all the more so if due attention be paid to position, and digital compression be applied to the main artery. These principles of treatment follow physiological lines. Injuries are serious in direct proportion as they in-

terfere with the exercise of healthy living functions; to restore and preserve them must be the surgeon's great aim in treatment; and he will be successful in direct proportion as he imitates and assists the natural processes.

To those who have noticed the omission of reference to so-called antiseptic surgery, I beg permission to address a few remarks. Life is the great antiseptic. Preserve it, restore healthy function, control by rest, position, and pressure, nerves, vascular, and muscular action, so as to minimize the material for, and the causes of, discharge, carry it off as it is produced by drainage tubes and absorbent dressings, and the repair of injuries proceeds like healthy nutrition, uninterruptedly and painlessly. That infection is always floating in the atmosphere, ready to settle in the shape of impalpable and implacable germs into any breach which may be made in the surface of a living body, is an idea which has never troubled me.

When, in 1867, Sir James Simpson was working out his acupressure, he applied to me for some information, suggested to him on reading my papers on "The Present State of Surgery in Paris," just previously published in *THE LANCET*. To illustrate one point, I requested my then house-surgeon to tabulate all the operations of any moment which I had performed during his tenure of office, a period of about two years and nine months, during which I had discarded poultices, water dressings as little better, and dressed wounds mainly by rest, position, and pressure with pads of dry lint. Excluding a large number of minor operations, all of which were successful, the total reached 107 operations, amongst which were three of lithotomy, ovariectomy two, fistula in ano twelve, trephining skull one, removal of bony sequestra six, ligation and division of varicose veins two, removals of female breasts twelve, removals of tumours sixteen, excision of elbow four, amputations of arm, wrist, thigh, leg; and ankle twelve, partial amputations of hand and foot twenty-five, with the result of three deaths in 107 operations, an average of my general surgical experience. The prescription to rub strong carbolic acid into the innermost recesses of a compound fracture, to pursue and kill the germs; the warning that an antiseptic dressing may lose all its potency through a hole no bigger than a pin's point in the investing mackintosh, admitting countless germs; that a dressing must be changed so soon as a little discharge permeates it, lest a septic channel be established for the ubiquitous and maleficent vibrios; that these will settle down as a swarm from the air on a granulating sore if the spray be not kept in action while it is dressed—are a few of the fallacies which have never had any dread for me. That as accessories to wound treatment antiseptics possess real value is an old truth, for insisting on which the world will ever be indebted to those from whom I have felt compelled to express qualified, but material, dissent. Their error has consisted in exaggerating incidents and underrating essentials; in predicating from experiments on dead organic matter the action of living tissues; in pretending to found a new surgery; in under-estimating truths which may not have the allurements of novelty or of speculative generalization, but which are none the less demonstrably sound foundations of surgery as a science, one and indivisible.

If, dealing with facts and principles, I have not mentioned authors by name, it has been for two reasons. I have been anxious to steer clear of personal controversy, which is one of the most formidable obstacles in the way of calm discussion; and it would have been impossible to refer to some authorities without seeming, but unintended, disregard of others.

Far from underrating the importance of the literature and history of the subject, I feel very deeply that if it had been better known, there would be less necessity for combating errors long since exposed, and insisting on truths inadequately appreciated or undeservedly forgotten.

Addressing myself, as by your permission I have had the privilege of doing this evening, to the Medical Society of London, I have felt that this was no occasion for a display of surgical erudition; I have rather fixed upon it as a good opportunity to elicit, by plain statement, an expression of opinion to test the possibility of agreement, after elimination of unsubstantial differences, on the essential unity of surgical principles in the treatment of wounds and fractures.

HOSPITAL PRACTICE, BRITISH AND FOREIGN.

Nulla autem est alia pro certo noscendi via, nisi quamplurimas et morborum et dissectionum historias, tum aliorum tum proprias collectas habere, et inter se comparare.—MORGAGNI *De Sed. et Caus. Morb.*, lib. iv. Proœmium.

MIDDLESEX HOSPITAL.

SURGICAL CASES.

(Under the care of Mr. A. CLARK.)

THE following cases which have lately been attending in the out-patient room present some features of interest.

CASE 1. *Chancre of Lower Lip, followed by Secondary Symptoms.*—E. B—, aged twenty-two, attended first on Dec. 29th, 1881, complaining of a hard swelling underneath her jaw. It did not take much consideration to decide that this was a glandular enlargement secondary to a sore on the lower lip, and the sore was a typical Hunterian chancre. The patient herself attached but little importance to the sore, which she stated she had had several weeks, but it was the hard increasing swelling which alarmed her. The girl's explanation of the lesion was that in the course of her employment, filling pickle-tins, she had accidentally cut her lip with a sharp edge. She declared she had kissed no one except a young man to whom she was expecting shortly to be married, and who was seen by Mr. Clark, and found to be perfectly healthy. The patient herself had always previously enjoyed good health, and there was no reason to believe that she had knowingly exposed herself to syphilitic infection; her own statement and that of her mother, who accompanied her, were perfectly straightforward. The treatment adopted was a drachm of the solution of perchloride of mercury three times a day, and in a week there was a marked improvement, in three weeks the chancre had all but healed, and the glandular enlargement much reduced, but then a rash appeared and ulcerated throat, and she has gone through the ordinary course of syphilis. Considering herself well on June 8th, when she discontinued her attendance of her own accord, only, however, to return with palmar psoriasis on July 8th, for which iodide of potassium was prescribed, and this she still continues to take.

CASE 2. *Abscess of the Parotid Gland.*—A. G—, aged fifty, first came on May 18th, 1882, with considerable enlargement about the right parotid, which she stated had been coming for several

months. It was in the main hard, but there were several soft fluctuating nodules projecting from it; there was some enlargement of the submaxillary lymphatic glands and several carious teeth, but of these the patient did not complain. The diagnosis was between glandular abscess affecting the right parotid and enchondroma of the parotid. A mixture of carbonate of ammonia and chincona was ordered, and locally an ointment of belladonna and iodide of potassium was applied. For the next two or three weeks the swelling continued to get harder and larger, and it was not until Aug. 31st that it burst, and then it rapidly disappeared, leaving a small discharging sinus. The patient always declined to have anything done to her teeth.

CASE 3. Enlarged Glands surrounding the Carotid Artery and simulating Aneurism.—E. B—, aged thirty-three, presented herself on June 26th complaining of pain in the left side of her neck, the result of a blow there ten day previously. There was evident enlargement on that side and some induration around the carotid artery, and with each beat of the heart the tumour expanded in every direction; there was no redness of the skin, not much tenderness on ordinary manipulation, and no perceptible difference in the two radial pulses. There was some enlargement of the cervical glands; the diagnosis was between aneurismal dilatation of the carotid and glandular abscess. The former seemed the more likely. A local application of belladonna and iodide of potassium was ordered and a tonic given internally. She was seen again on June 29th, when there was no perceptible difference. On July 6th the objective signs were the same, but the patient complained of more pain, inability to sleep, and an unpleasant pulsation; she was therefore admitted as an in-patient, and a subsequent exploratory incision proved the case to be one of enlarged glands entirely surrounding the artery.

CASE 4. Deep-seated Abscess in Axilla.—L. C—, aged fifty-six, presented herself on April 10th, complaining of intense pain in her right axilla. She attributed it to a twist some three weeks previously, following which the pain began, and had expected it would get better of itself, but it daily increased in severity, and her health was beginning to be affected from want of sleep, so she reluctantly came to the hospital. There was some fullness over and below the pectoralis major, and extreme tenderness both there and in the axilla, but there was no specially tender spot, no redness of the skin, no fluctuation, no history of a rigor, and no glandular enlargement to be felt. It was believed to be a deep-seated abscess, so a long narrow bistoury was carefully introduced, and some laudable pus escaped; the opening was then enlarged by means of dissecting forceps. There was a free discharge; and the next day the patient expressed herself as being quite well; nothing but a sinus remained, which healed by the 27th, and the patient was discharged. She, however, returned on June 15th, with some œdema of the arm, which, under local friction and the administration of quinine and iron, disappeared.

TWO CASES OF FRACTURE OF THE SKULL IN YOUNG PATIENTS.

(Under the care of Mr. GEO. LAWSON.)

The two following cases show from what severe injuries of the head young patients may recover. In the first case there was an indented fracture of the skull; and although there was a considerable depression of bone, yet, with the exception of a slight drowsiness for a few hours after the accident, the child had no cerebral symptoms, and left

the hospital after three weeks quite well; indeed, he was only detained in the hospital because it was probable that some head symptoms might arise. The second case is very remarkable. The child fell the height of seventeen feet from a loft on to the stones below. There was without doubt a fracture of the vertex extending into the base of the skull, as was evidenced by the repeated vomiting of blood, the altered shape of the skull, and the intense and prolonged coma. The child was admitted on September 30th in a state of deep coma, and she remained in a state of unconsciousness five days, until October 5th, and unable to swallow any food except three teaspoonfuls of milk on the afternoon of the 4th. During this period she was fed with nutrient enemata. To account for this prolonged insensibility there must have been severe brain lesion, and yet the child has recovered, and now, without any apparent discomfort, is able to play with her toys, and behave as if she suffered no inconvenience from the injury. Another interesting point in the case is the time which elapsed before she was able to speak. It was not until the sixteenth day after the accident that she could be induced to answer any question, although, apparently, she often tried to say something.

CASE 1. An Indented Fracture of Skull; very Slight Head Symptoms; Recovery.—John G—, aged sixteen months, was admitted into Bird ward on July 8th, 1882, with an indented fracture of the skull. Shortly before being brought to the hospital the child fell off a high stool, and in his fall his head came into direct contact with the abrupt end of the leg of another stool which had been overturned.

State on admission.—There was a depression in the skull just above and to the left of the occipital protuberance, which corresponded exactly to the end of the stool. The depression was about one-tenth of an inch deep, visible to the eye, and the sharp edge of the surrounding bone could be easily felt with the finger through the integument. The child seemed drowsy, but, with this exception, there were no cerebral symptoms. The anterior fontanelle was not completely closed, but the posterior fontanelle was quite filled in with bone. An ice-bag was applied to the head, and the child kept quiet in bed.—9th: The child seems very well, and in no way affected by the accident. He soon recovered from the drowsiness, and eats and sleeps well, and plays well.—20th: The child has been kept in the hospital lest head symptoms might arise. He is very well and cheerful. The indentation, so marked on admission, is much less, the depressed bone having been partially raised towards the surface.—31st: As the child seems quite well he was discharged from the hospital. There was still a slight depression of the bone.

CASE 2. Ethel D—, aged six, was admitted into Bird ward on Saturday afternoon, September 30th, 1882, having just fallen from a stable loft on to the stone paving below, a height of seventeen feet. She was standing on a chair playing, when she tipped forwards and fell head foremost on to the paving, her head first striking the ground.

State on admission.—The child was in a state of profound coma. The left side of the head was very large from an extensive hæmorrhage beneath the scalp. Soon after her admission she vomited a quantity of blood, and twice the next day threw up blood, but in less quantity. She was unable to swallow, and a teaspoonful of milk put into the mouth ran out again. Ordered an ice-bag to the head, and to have an enema of beef-tea and an egg, an ounce and a half every four hours.—Oct. 1st: The child still lies in a state of coma. Has

vomited once some blood. Neither moves nor speaks. To continue the enema, as she is unable to swallow.—2nd: The child remains in the same unconscious state, but she shifts her position and draws up her legs, and is at times restless. She is unable to swallow. To continue the enema.—3rd: Still unconscious and unable to swallow; and although repeated attempts are made to give the child a teaspoonful of milk, it always runs out of the mouth. As she is very restless, and with difficulty kept in bed, a wooden frame has been placed around the bed, to keep her from falling out. To continue the enema.—4th: To-day the child seems to be better. She is still very restless. During the afternoon she swallowed about three teaspoonfuls of milk. As the bowels have acted twice the enema is given at longer intervals.—5th: The improvement has continued. She has taken half a teaspoonful of milk by the mouth, and is gradually regaining consciousness, and will look up when spoken to. The swelling of the side of the head is much diminished, but still there is fluctuation beneath the scalp on the left side of the head. To continue enema.—6th: The child is much better; she sits up in bed, and takes food. Ordered chicken, and milk with bread-and-butter. Omit enema. She has not yet spoken, although she clearly understands what is said to her. From this time the improvement continued. She began to play with her toys, and to take an interest in things around her. She would frequently try to speak, but was apparently unable to do so. The first time she spoke was on October 15th, when she answered "Yes" to a question put to her by the nurse. For the next two or three days she could only be induced to say "Yes" or "No."—24th: The child is now rapidly approaching convalescence. She talks freely, and plays all day on the bed with her toys. The blood beneath the scalp has been absorbed, and the left side of the head (the part on which she fell) is considerably flattened, but it is gradually regaining its natural shape. She has never complained of any pain in the head. There have been no paralytic symptoms either of the extremities or any of the parts supplied by the cranial nerves. The child will be kept for some weeks under observation in the hospital.

LEEDS PUBLIC DISPENSARY.

CASE OF ANEURISM OF BASILAR ARTERY; RUPTURE; DEATH; NECROPSY; REMARKS.

(Under the care of Mr. C. J. WRIGHT.)

For the notes of the following case we are indebted to Dr. Hudson.

William —, aged sixteen, currier, was found in the street in a fit, at 4 P.M., March 12th, 1882. He was conveyed to an inn and given some whiskey, after which he attempted to walk home. After going about forty yards in a semi-stupefied condition, he fell down insensible, not convulsed, and was taken home by a policeman, vomiting profusely on the way. At 7 P.M. he was seen by Dr. Hudson. He was then lying on his back, his face pallid and covered with perspiration, as also the rest of the body; pupils dilated, equal, not responding to light, no apparent loss of muscular power, limbs flaccid. He could not be aroused by loud speaking; pulse 79, full, compressible; respiration 26; temperature 100.4°. There was no paresis of the sphincters, nor any loss of blood from the ears or mouth. The nostrils were partly filled with clotted blood, and a trace of the same was on the upper lip. There was no evidence of fractured skull or other injury. At the bed-side was some vomit slightly and equally mixed with dark blood. There

was no injury of a former date, nor history of any illness to be elicited, neither was there suspicion of foul play. The head was shaved and an ice cap was applied. The vomiting having ceased, six grains of calomel were placed on the tongue. At 10.30 P.M. he was seen by Mr. Wright. He could now be roused, and answered "Yes" to a question about pain, putting his right hand to the frontal region and keeping it there. The pupils were normal and acted well; there was no paralysis, no return of vomiting, and the bowels had acted freely. Pulse 80, diicrotous; respiration 24; temperature normal. Perfect quiet was enjoined, soda water and milk were given, and the ice was continued.—13th: More conscious; complains of great pain in the frontal region with intolerance of light, and of nausea. He remembers feeling "dizzy" and falling, nothing further; urine normal. Ordered an effervescing draught, with ten grains of bromide of potassium every three hours.—14th: Has not slept owing to the frontal cephalalgia; looks very pallid, is warm, and has not vomited again. No blood in nostrils; no melæna. Respiration and temperature normal; pulse 80, firmer. Ordered two ounces of compound senna mixture, and a blister to nape of neck.—16th: Has slept two hours, and had less pain; bowels very confined; passes water freely, and has perfect control over the emunctories. To continue with draught and have a powder with six grains of calomel and a drachm of compound jalap powder at bedtime.—18th: The frontal pain alone complained of, and which entirely prevents sleep; no vomiting. Temperature normal. To have nightly a draught of three grains of chloral hydrate, with twelve grains of bromide of potassium.—23rd: Still intense frontal pain. A seton inserted in nape of neck. To have seven grains of iodide of potassium three times a day, and mercurial ointment applied to the arm.

April 4th: The pain continuing, though not so severe as before, a seton was put in the nape of the neck, and the mixture increased to twelve grains of iodide of potassium three times a day. The draught at bedtime was continued, as he only slept after taking it.—12th: Has less pain, eats well, and sits up in bed daily.—14th: No pain for two days. The ointment to be discontinued, and the seton removed.—20th: Was out of bed two hours.—24th: Reported by his mother to have had a "fit" at midnight, not being convulsed but falling suddenly on the floor. He remained unconscious forty-five minutes, and continued "dazed" for hours afterwards. He vomited shortly after the "fit." He still seems stupid, and complains of great pain over the left orbit, whereas previously it was referred to the whole frontal region. Bowels unmoved for two days. To continue mixture and draught, and two compound colocynth pills at bedtime.

May 1st: Has no pain, and been up for the first time since the "fit."—11th: Having had no pain for twelve days the iodide was reduced to two grains thrice daily, and the draught discontinued. 12th: Attended at the dispensary, walking well, and only looking pallid. Ordered to Ilkley. 13th: Went to the theatre, and while down in the vestibule between the acts had a "fit," at 10 P.M.; was taken to the General Infirmary and expired immediately after admission, at 10.30 P.M.

Necropsy, forty-two hours after death.—A large quantity of clotted and semi-fluid blood covered the whole surface of the brain, especially the base, extending over and down below the medulla oblongata and through the transverse fissure into the lateral ventricles. An aneurism about the size of a small bean was found at the junction of the basilar with the left posterior cerebral artery, which

had given way in its lower wall, the opening being about the size of a large pin's head. The coats of the aneurism were extremely thin, especially around the ruptured point. There were no signs of any former fracture of the skull. Other organs healthy.

Remarks by Mr. WRIGHT.—Although the cases of cerebral aneurism upon record are somewhat limited, they are probably in reality more common than is supposed, owing to the real causes of some hæmorrhages over the brain being either overlooked or never ascertained; such cases being either not examined after death, or simply set down as 'under the head of "apoplexy." The basilar artery appears to be the most usual seat for the development of a cerebral aneurism, which probably can seldom, if ever, be diagnosed with certainty during life. In the above case the main symptoms were the epileptiform attacks, the fixed and persistent pain in the forehead, giddiness, with consequent sleeplessness, and intolerance of light. The patient, aged sixteen, was young for disease of this character. Of sixty cases of cerebral aneurism mentioned by Dr. Tanner,¹ including fifty-two cases collected by Dr. Brinton,² the average age was forty-one, the youngest patient being fourteen, the oldest sixty-five. It may be a question how far the first attack, which took place in the street, and the second during his illness, may have been due to some oozing from the aneurismal sac. No trace or proof of this, however, was found after death. It is worthy of note that the fatal seizure due to the rupture took place, not during the excitement of a sensational play at the theatre, but between the acts—i.e., during physical exertion subsequent to the mental effort.

STANLEY HOSPITAL, LIVERPOOL.

UNUNITED FRACTURES OF HUMERUS, RADIUS, AND ULNA, SUCCESSFULLY TREATED; REMARKS.

(Under the care of Mr. ROBERT JONES.)

CASE 1. *Ununited Fracture of the Right Radius.*—J. K—, aged forty, a sailor, fractured his right radius on the way to New Zealand. The captain of the vessel undertook its treatment for the first two months, which consisted in the application of the usual side splints. The patient on landing procured a surgeon, who proclaimed non-union, and persisted in the use of splints for a further period of six weeks. No success, however, accompanied this, and, in J. K—'s own words, "For four months once a week the doctor took hold of my arm and elbow and shook it for five minutes." The patient subsequently returned to England; and in August, twelve months after his mishap, he was admitted as an out-patient to the Stanley Hospital. The radius was ununited at the junction of the middle with the upper third. Around the fractured ends some thickening was perceptible. He complained of pain at night, more especially when the previous day had witnessed much use of the arm. He was quite unable to do heavy lifting, and any attempt at closing the hand firmly produced "shooting pains" around the elbow. Furthermore, a dependent position of the arm invariably gave rise to an unbearable feeling of fullness at the seat of fracture.

CASE 2. *Ununited Fracture of the Ulna.*—R. S—, a sailor, aged fifty, became in October last an out-patient at the hospital. On examining him an ununited fracture was found at the middle of the ulna. The ends were freely movable and thick-

ened, and the skin over the seat of fracture much hypertrophied. The subjective symptoms were, pain at night, loss of power in the limb, and violent neuralgic pains during damp weather. He gave the following history: Twelve months previously he broke his arm in a pugilistic encounter on the plains of the Argentine Republic. It was plastered next day by a practitioner, who advised the removal of the dressing in about a fortnight. This injunction the patient obeyed while at sea, but necessarily with unpleasant results. On his arrival at a foreign port, a doctor applied more plasters and advised more rest. For five weeks this treatment was adopted with no improvement save in the matter of pain. Three months later the patient arrived in England, where he immediately sought advice from a medical gentleman, who proposed cutting down upon the fractured ends and excising them. This procedure he would not submit to.

CASE 3. *Ununited Fracture of the Surgical Neck of the Humerus.*—J. R—, fifty-six, was admitted an out-patient for fracture of the surgical neck of the humerus. He had met with the mishap the day before, and on his admission the contusion and swelling were so formidable as to render the application of splints quite out of the question; nor were these appearances sufficiently modified to admit of the use of supports until the ninth day, when the arm was immovably fixed. With the exception of the usual weekly trimming, this fixity was undisturbed for seven weeks, at which time there was absolutely no union. Three weeks more of anxious waiting and withal no change.

Remarks by Mr. JONES.—In the treatment of these cases I followed the method introduced to the profession by Mr. H. O. Thomas—that known as "percussion." Of this there are two varieties. The one consisting in severely percussing the limb over the seat of fracture at long intervals; the other in its daily but gentle performance. Whichever plan be adopted elastic bands should also be tied above and below the fracture to induce local congestion and thereby facilitate the reparative process. More especially is this necessary at night time, when the circulatory system is less active than during the day. The hammering is performed with an instrument covered by an indiarubber cap, so as not to lacerate the soft structures. In its absence, however, anything almost will suffice. In Case 1, the bone being somewhat deep seated, I adopted the method of severe hammering, which I performed once a week. The patient tolerated it very well and complained but little of the pain, although the indiarubber tubes tied round his arm at night made him very restless. I applied no splints, but merely permitted the carriage of his arm slung in hammock-like fashion. This lasted five weeks. After each beating a good deal of swelling and even some contusion marked the occasion. At the end of the fifth week, having noticed a decided thickening of the ends of the bone, I applied splints for four weeks, removing them in time to find union complete. Case 2 is more interesting because more rare. In treating the patient I dispensed with the elastic tubes, and the bone being superficial it was, of course, better to try the gentle mode of percussion than that adopted in Case 1. Accordingly I hammered twice a week and kept the splints firmly applied. In a little over four weeks union was firmly established. In both these cases the treatment gave the patients hardly—if indeed any—more inconvenience than they had already endured. Case 3 differs from the others in being a less confirmed non-union. The patient was ten weeks in splints after a primary delay of nine days; and it is impossible to say but that another month's continuance would have pro-

¹ Practice of Medicine, sixth edition, vol. ii., p. 455.

² Transactions of the Pathological Society, vol. iii., p. 47. 1852.

duced union. I thought it best, however, not to trust to this alternative, and, using my flat for a hammer, I worked away twice a week for nearly two months, with completely satisfactory results. I may mention that the elastic tubes may be applied immediately after the gentle method, but it is best after the severe mode to wait until the local irritation commences to subside, and thereby prolong it. Should the contusion be very marked, it would, of course, be unwise to apply them at all. As a matter of detail, I may add that the tubing should not always be tied to the same spot, or else ulceration may result. Generally speaking its application at night-time is quite sufficient, and affords the arm very acceptable respite during the day.

SEAMEN'S HOSPITAL, GREENWICH.

RUPTURE OF LIVER; THROMBOSIS OF HEPATIC VEINS; EMBOLISM OF A BRANCH OF LEFT PULMONARY ARTERY; PLEURISY; DEATH; NECROSIS; REMARKS.

(Under the care of Mr. G. H. MAKINS.)

The following case came under Mr. Makins' care while doing duty for Mr. W. Johnson Smith.

On Sept. 30th, at 3.30 p.m., J. R.—, aged twenty-four, a laborer, while in a state of intoxication, was run over in the street by an empty cart, and taken at once to the hospital. The wheel, it was said, had passed over the abdomen.

On admission he was in a state of collapse, and could not be got to answer any question; the countenance and lips were extremely pallid, the pupils dilated, the extremities very cold, and the pulse almost imperceptible. He was put to bed, hot bottles were applied, and a hypodermic injection of brandy (twenty minims) was given. At 8 p.m. he was much improved in appearance, answered questions rationally, but in an excited manner; smelled strongly of spirits; lay on right side. He complained of great pain and tenderness in the epigastrium, but was able to turn in bed without much suffering; no abnormal abdominal dulness; had been sick twice since admission; respiration 30; abdominal wall moving freely; no sign of fractured ribs; temperature 97°; extremities still very cold; pulse 130, small, but quite perceptible. Hypodermic injection of one-third of a grain of morphia. The bowels were moved some time after admission. The patient had a quiet night, but slept little, and next morning he complained of much pain in the epigastrium. The abdomen was slightly swollen and tympanitic; no abnormal dulness in flanks; temperature 98.4°; skin still pale, and hands felt cold; pulse 150, small; respiration 32, chiefly thoracic, but abdominal wall still moved; tongue furred, but moist; no further vomiting. One teaspoonful of brandy was given every half hour; milk diet; ice; one grain of opium pill was given, to be repeated in half-grain doses every four hours. At 8 p.m. the opium had relieved pain; still pallor; temperature 97°; hands very cold; pulse 150, very small; respiration 44, entirely thoracic and extremely shallow.

On Oct. 2nd he had slept fairly; lay on his back, sometimes with knees raised, sometimes down; slight pain and tenderness chiefly in epigastrium; abdomen as yesterday; respiration 38, thoracic, but much less shallow than last night; temperature 96°; skin moist; pulse 138, stronger and better volume; tongue moist, covered with white fur. Took plenty of milk. On the third he had slept the greater part of the night, but in the morning he complained of pain on the left side of the chest;

abdominal wall hard; abdomen slightly tympanitic, but no marked swelling; no tenderness anteriorly, and no abnormal dulness; respiration 30, entirely thoracic; pulse, 120, steadier and stronger; temperature 99°; skin moist; tongue furred, moist; no sickness; bowels confined. 8 p.m.: Pain in left side very severe; respiration 40, very jerky and shallow; temperature 101.5°; pulse 140; chest somewhat hyper-resonant anteriorly; breath-sounds exaggerated, and some moist rales; patient not in a condition to be lifted to examine back. On the 4th he complained much of pain in the left side; face looked pinched; no cough nor expectoration; respiration 32, very shallow; pulse 132, stronger than last evening; temperature 101°. The breathing became rapidly more impeded, and the patient died in the afternoon.

Necropsy.—Abdominal cavity contained about a pint of fluid blood, one or two coils of small intestine slightly granular on surface, and the whole somewhat distended by flatus, but no further signs of peritonitis. At the right extremity of posterior border of the liver a laceration existed, a bruised portion of tissue occupying an area about the size of a small orange extending into the substance of right lobe; this was of an ochre-yellow color, and internal to it were several fissures in the apparently healthy hepatic tissue containing blood-clot; externally it formed one of the boundaries of an incomplete cavity, the walls of which were made up in addition by the anterior fold of the coronary ligament, the diaphragm and the right supra-renal capsule, together with some recently effused lymph. This cavity contained fluid blood and debris, and the walls were deeply bile-stained. The hepatic veins leading from and traversing the bruised area were occupied by firm dark blood-clot, and this condition was found to extend back as far as their entrance into the inferior vena cava, the lining membrane of the veins being roughened and vascularized. On microscopical examination the yellow area of hepatic substance was found to be in the condition known as "coagulation necrosis," and the walls of the hepatic veins and the tissue surrounding them largely infiltrated with small-celled inflammatory new growth. The other abdominal organs were normal. Lungs: The lower lobes on either side were much collapsed, and at the extreme base completely void of air, sinking in water. In the upper part of the lower lobe on the left side was an infarct, about the size of a small orange, wedge-shaped, with the base abutting on the surface, and in the main branch of the pulmonary artery to lower lobe was an embolus about three-quarters of an inch in length, decolorized, not attached to the arterial wall, and when incised disclosing a central cavity containing softened matter; this embolus apparently having its origin in the thrombosis of the hepatic veins. The left pleural cavity contained a considerable effusion of blood-stained fluid, while recent lymph covered the pleural surface of the infarct, also united the lower part of the fissure and covered the entire base of the lung, which was adherent to the diaphragm. Right pleura, heart, and pericardium were normal.

Remarks by Mr. MAKINS.—The above case is recorded as affording an example of a termination to a rupture of the liver not often described, and of which mention is omitted in most of the text-books, although the arrangement of the veins would seem particularly favorable to its occurrence. The patient had escaped the primary dangers of shock, hæmorrhage, acute septicæmia, or severe peritonitis; and although still liable to the supervention of the two latter, yet in the absence of the pulmonary complication dependent on the thrombosis and subsequent embolism, he undoubtedly stood a chance of recovery; the more so since reparative

processes preparatory to the localization of the damage had already commenced at the seat of injury.

NORTHAMPTON GENERAL INFIRMARY.

A CASE OF ACUTE CHOREA COMPLICATED BY PERICARDITIS, ENDOCARDITIS, CELLULITIS, ETC.

(Under the care of Dr. FRANK BUSZARD.)

FOR the following interesting notes we are indebted to Mr. J. Oswald Lane, assistant house-surgeon.

J. D.—, aged fifteen, was admitted on June 19th into the hospital with the following history:—He is one of a family of eight children, all of whom are rather delicate, but the patient himself has never been laid up before the present illness; has never had rheumatism; no history of shock or of overwork of mind or body; has always been a sharp lad, and no members of the family have been affected with nervous disease. The first appearance of the present illness showed itself on June 6th, when he was seized during the night with excruciating pain in the right leg, followed the next morning with “snatching” of the muscles of the right half of the body, though both sides of the face were affected. These movements became gradually more marked and general. Two days before admission he first began to wander, while at times insensible; at others very noisy; cracking of skin also noticed.

On admission the choreic movements were general and of the most marked form, especially so of the face and arms. He was very noisy, crying out furiously; at times sensible, but unable to answer in articulate sounds. Skin very dry and cracked, lips fissured, tongue brown, covered with sordes. There were distinct signs of hyperæsthesia; pupils dilated and sluggish to the action of light. Pulse 120; temperature could not be taken.

June 20th.—Passed a very noisy and restless night, delirious at times though occasionally sensible; spasmodic movement of the muscles still just as marked, and is unable to articulate words or swallow.—21st: Much quieter, whilst the choreic movements have almost stopped; power of articulation and swallowing just the same, while the respiration is very jerky; there is a distinct pericardial murmur with no increase of dullness. Pulse 124. Urine shows an increase of urea.—23rd: Movements still present; can now swallow liquids; sometimes utters articulate sounds and nods when asked questions. Area of cardiac dullness increased, friction; bronchitic sounds; signs of inflammation in left forearm; also of right wrist and hand. Pulse 130; respiration 35. Temperature, morning 99° 6'; evening 98° 6'.—25th: Choreic movements abated. Can now say some few words, such as “Mother,” “Nurse,” “Yes,” “No.” Sordes less; bronchitic sounds to be heard, while the cheeks are flushed. Incision was made into the left forearm, when a large amount of pus was evacuated. Skin still cracked. Pulse 128; respiration 38. Temperature, morning 99°; evening 100°.—26th: Pulse 133; respiration 32. Temperature, morning 100°; evening 100° 2'. Cellulitis still increasing, as also the area of cardiac dullness.—27th: Temperature, morning 100°; evening 100° 2'.—28th: Temperature, morning 100°; evening 100° 4'.—29th: Temperature, morning 98° 8'; evening 102°. A large amount of purulent discharge from the incision made into the left forearm; right hand swollen, but no feeling of fluctuation. Tongue cleaner; appears better though still extremely prostrate;

choreic movements have entirely disappeared; he is able to speak more distinctly, but only a few monosyllables. Bowels confined; appetite improved. Respiration 30, at times irregular and labored. Pulse 132.—30th: Temperature, morning 99°; evening 102° 2'. Discharge copious.

July 1st.—Temperature, morning 102°; evening 101° 8'.—3rd: Temperature, morning 100°; evening 102° 4'. An incision was made into the palm of the right hand, when a large amount of curdy sanguineous pus exuded. Abdomen tympanitic; heart's area of dullness has gradually increased, no endocardial murmur to be heard; appetite improved. Pulse 126, not wiry; respiration 32.—4th: Temperature, morning 99° 6'; evening 103° 8'; discharge copious.—8th: Temperature, morning 100°; evening 103° 2'. Discharge from right hand, though copious, has diminished in quantity, some swelling of the right arm below elbow; no joints affected; area of cardiac dullness has increased downwards, and towards the axillary line no exocardial murmur, but a distinct soft systolic murmur can be heard at the apex; tongue fairly clean; takes nourishment well; some flatulæ. Pulse 128; respiration 32.—9th: During last night he perspired copiously and does not seem so well this morning; this was accounted for by a collection of deep-seated pus in the right forearm, which was evacuated by incision. Temperature, morning 101° 2'; evening 102° 2'.—13th: The patient has improved the last few days; his temperature has gradually defervesced; his speech is much improved, as he now talks correctly but slowly; expression brighter and tongue clean. Temperature, morning 99°; evening 99° 2'.—19th: The last two days his febrile symptoms have become marked, while he complains of tenderness in right palm of hand, and some slight pain in right thigh. Temperature, morning 98° 8'; evening 102° 2'.—20th: Another incision was made into the right hand, giving a free exit for purulent matter; during the next few days the febrile symptoms greatly diminished, and he improved rapidly in general health.—30th: From the time of the last notes the patient has gone on gradually improving, his temperature has been normal for several days, and all the discharge has stopped. He is now allowed out of bed; the systolic murmur has become much more marked, and can be heard over a larger area than previously. He was discharged on August 6th convalescent, the systolic mitral murmur alone remaining.

Medicinal treatment.—During the first ten days after admission small doses of chloral and digitalis were administered, followed then by the liquor cinchonæ (Battley's) in five-minim doses every four hours. He was kept on the latter treatment for one week, when sulphate of magnesia in twenty-grain doses every four hours was administered. This was continued for three weeks, when iron and quinine were given him till his discharge.

Remarks.—This case here recorded has several features of interest in connection, amongst which may be enumerated:—1. Marked choreic movements developed themselves previous to any apparent signs of pre-existing period of endocardial mischief, inasmuch as the physical signs which manifested themselves on the third day after admission were those of commencing pericarditis, as the subsequent history of the case will show. 2. Pericarditis followed by endocarditis presented itself without any assignable cause; there was an entire absence of any rheumatic history in *propria persona* or hereditary. 3. The severe phlegmonoid inflammation of the cellular tissue which developed itself; this probably being of a pyæmic nature, dependent upon the existing cardiac complication. 4. The acuteness of the attack in the male sex, with subsequent recovery.

UNIVERSITY COLLEGE HOSPITAL.

TWO CASES OF INCREASED EYEBALL TENSION; ONE
REDUCED BY ESERINE, THE OTHER BY ATROPINE.

(Under the care of Mr. TWEEDY.)

Among the cases lately presenting themselves in Mr. Tweedy's clinique were two of considerable therapeutical and pathological interest. In both the tension of the left eye was greatly increased, though from different causes. In one the tension was reduced to normal by means of a pupil-contractor, eserine; while in the other a similar result was produced by a pupil-dilator, atropine. In the first the disease was intermittent glaucoma; in the second, recurrent iritis. The interest of the case is increased rather than diminished by the fact that such examples are by no means infrequent, and their gravity by the fact that a mistaken choice might be disastrous. To employ atropine in glaucoma and eserine in iritis would, besides aggravating the existing symptoms, in all probability induce irreparable mischief. Mr. Tweedy alleged that it had become too much the fashion to regard increased tension of the globe as always identical with glaucoma. This is as irrational as it would be to regard ascites as always and only indicative of cirrhosis of the liver. The second of these cases showed that there may be a high degree of hardness of the eyeball, and yet an absence of glaucoma. In glaucoma the increased tension usually supervenes on changes affecting the drainage apparatus of the anterior segment of the globe, checking elimination, whereas the increased tension occurring in iritis and allied conditions primarily and chiefly depends on engorgement of the vascular tunics of the interior of the eyeball and on the formation and accumulation of inflammatory products. Eserine and other myotics could not, it was stated, be looked upon as the rivals of iridectomy or sclerotomy in glaucoma, they were rather adjuvants, and at most alternative in cases where operation was not imperative or was otherwise impracticable. On the other hand, as glaucoma is a cumulative condition the judicious employment of myotics might correct the vice on which the malady essentially depends, and thus ward off an actual outbreak.

For the following notes we are indebted to Mr. F. Knight, ophthalmic assistant.

CASE 1. Intermittent Glaucoma; increased Tension rapidly reduced by Eserine.—Maria B—, aged fifty-five; on August 21st the patient was seized with severe pain across the top of the head, in the forehead, and left eye. For a week this pain was constant and prevented sleep. On August 28th a blister was applied behind the left ear, and this seemed to relieve the pain considerably. After a day or two the pain returned, and up till Sept. 11th the pain recurred nearly every day, each attack lasting eight or ten hours. During these attacks the patient could not bear any light and had to have the room darkened. Objects looked foggy. On September 11th she came to the hospital for dimness of the left eye and neuralgia. The left pupil was slightly larger than the right, the tension normal and equal; V=20-70 in the right eye, and 20-200 in the left. The left optic papilla was "shallowed." From the history rather than from the physical signs a diagnosis of intermittent glaucoma was made. Quinine mixture was ordered. On September 17th the patient was seized with an attack of pain, and when seen on the following day the tension was increased to T + 2, the vision had greatly diminished, the media were hazy, and there was visible pulsation of the central artery of the retina. A drop of a solution of sulphate of eserine (two grains to the ounce) was applied to the con-

(5)

junctiva of the left eye, and in half an hour the tension had sunk to normal, the pain had ceased, and the sight had improved. Eserine was ordered to be applied twice a day. No recurrence of pain, increased tension, or obscuration having occurred in the interim, a solution of nitrate of pilocarpine (two grains to the ounce) was, on October 5th, substituted for the eserine as being less costly, and in some cases as effectual. On the 9th the eye was not so well, the tension was increased, the pupil semi-dilated, and the sight was "misty" again. Eserine was applied once more, and in half an hour the tension was normal, the pain gone, and the sight clearer. Since then eserine has been used twice a day, and the sight and general condition of the eye have steadily improved.

CASE 2. Recurrent Iritis; Increased Tension (T + 2); Reduced by Atropine.—S. O—, aged forty, a tailor, was seized with violent pain in the right eye on waking on the morning of Oct. 24th, 1881. The pain continued till Nov. 7th, when he applied at the hospital. He then had marked kerato-iritis with many posterior synechiae. The pharmacopoeial solution of atropine, applied many times at short intervals, failed to dilate the pupil. Leeches were applied, a mercurial and colocynth purge was given, and atropine was instilled every two hours. The pain speedily subsided, and in a few days the eye was apparently recovered. The left eye was then attacked, but soon got well. In the following January episcleritis appeared in the right eye, and continued some weeks. On February 23rd, however, the eyes were quite well; the acuteness of vision was normal. On March 9th there was another recurrence of iritis, with posterior synechiae in the left eye, but this attack responded gradually to treatment, and on May 1st the patient resumed work, and continued to work with comfort till Oct. 14th. On the morning of this day the left eye was again attacked with recurrent iritis of a severe type. The patient applied leeches and poppy fomentations, but did not attend at the hospital till the 17th, when he had an extreme degree of kerato-iritis: the aqueous was turbid, the pupil greatly contracted and blocked with lymph, which extended over the whole surface of the iris and covered it. The tension was increased to T + 2. Atropine was applied at short intervals, and one grain of calomel and a quarter of a grain of opium were given three times a day. On the 19th the pain was less, the tension somewhat diminished, and the pupil was semi-dilated, exposing a narrow space between the edge of the iris and the circular mass of lymph in the pupillary area. Three days later, the same treatment having been continued, the pain had ceased; the pupil was rather larger, the cornea bright, the lymph gone from the pupil, and the tension was if anything subnormal, from inflammatory softening.

BRISTOL ROYAL INFIRMARY.

NOTES OF A SEVERE CASE OF STRAMONIUM POISONING;
SUBCUTANEOUS INJECTION OF MORPHIA; RECOVERY;
REMARKS.

For the following interesting notes and remarks we are indebted to Dr. Alfred Lendon, house-surgeon.

On August 10th, 1882, Rosina J—, aged seven, while at play with two sisters in a suburb of Bristol discovered some green berries, of which the three partook freely. Rosina, however, eating more than the other children. She returned home shortly after, and was noticed to be strange in her manner. Soon she became slightly, and finally very, delirious. On learning that she had eaten something, her parents gave her an emetic of mus-

tard, and then took her to a surgeon, who administered another of sulphate of zinc, neither of which acted. She was admitted into the Royal Infirmary, under Dr. Shingleton Smith, four hours after the occurrence, and her friends produced some leaves supposed to belong to the plant the berries of which she had eaten; this was recognized to be stramonium (*datura stramonium*, or thorn apple). Her symptoms were those of acute deliriant poisoning. The child was unable to answer questions, was extremely restless, rolling her head from side to side, and throwing her limbs about, so that she could scarcely be restrained in bed; she was talking incessantly and incoherently, and did not seem to recognize her friends, but evidently had spectral illusions. She was constantly picking the bedclothes and pawing the air. Her pulse was very rapid, her face flushed, and her eyes were frequently squinting, but not in any definite direction; the pupils were widely dilated. Her breathing was rapid, but not labored; its rate, and that of the pulse, could not, however, be counted, as she was so restless. An emetic powder, containing ipecacuanha and antimony, was administered in water, but failed to act, whereupon one-twenty-fourth of a grain of apomorphia was injected under the skin, which had almost immediately the desired effect. In the vomit at least 100 stramonium seeds were found, together with portions of the seed capsule, mixed with partially digested food. As her symptoms showed no signs of abating, and were very alarming, one-sixth of a grain of acetate of morphia was injected hypodermically after about twenty minutes' interval. This had the effect of quieting her in a few minutes; she soon slept; the pupils became of moderate diameter, though not contracted; the strabismus, however, continuing for four hours. When seen next morning she was much better, having passed a quiet night; there was no delirium, the strabismus had ceased, but the pupils were again widely dilated. The temperature, pulse, and respiration were normal, and also the urine; the skin throughout had been dry, in spite of her exertions, but no rash was seen, and the child did not complain of dryness of the throat. On the 11th she was sick twice after taking purgative medicine, more seeds being brought up, and when purged later on in the day, the stools also were found to contain seeds. On the 12th she was sick again, and seeds were still found. Subsequently nothing worthy of note occurred, and the patient was discharged on the 18th.

When shown a thorn apple the child recognized it, and stated that she had eaten the contents of ten. Her two sisters were also ill and rather light-headed during the night, but they recovered without any special treatment beyond emetics administered by their mother.

Remarks by Dr. LONDON.—The recorded cases of poisoning by stramonium are very rare, and I am unable to look up the particulars of two instances reported in 1837 and 1872, which are mentioned in Dr. Neale's "Digest." All that seems to be known is that while the symptoms closely resemble those of poisoning by belladonna and hyoscyamus, they commence sooner, are more severe, and terminate fatally in a shorter time. The only symptom which appears not to have been noticed usually in poisoning by these drugs is strabismus; on the other hand, no erythematous rash was seen, and no dryness of the throat or thirst was complained of. With regard to the quantity of the poison taken, the child's statement probably cannot be relied upon, nor have we any means of ascertaining whether it was even a fatal dose, but that the quantity was very considerable must be assumed from the alarming severity of the symptoms; more-

over, as the seeds were not altered in appearance, and presumably had not been acted upon much by the gastric juice, it is probable that only a small amount of the active principle which was actually present in the stomach had been absorbed into the system. The chief points of interest in the case, however, are the decided antagonism manifested by morphia to stramonium, both as regards the delirium and the condition of the pupil, and the speedy and complete relief afforded by this moderate dose of morphia. It may be objected that as the other children recovered without any special treatment, so, too, this child might have recovered; on the other hand, it must be remembered that they were not considered bad enough by their parents to be brought up for advice. It is also worthy of note that seeds were vomited as long as forty hours after the poisoning, the patient having been sick on three previous occasions, so that implicit reliance could not be placed on emetics only. I am unable to ascertain whether morphia has been previously used as an antidote either in human beings or in experiments upon animals. In the fourth edition of Guy and Ferrier's "Forensic Medicine" it merely says that the use of morphia is worthy of trial.

KASHMIR HOSPITAL.

CASE OF COMPLETE CONGENITAL OCCLUSION OF THE OS UTERI; OPERATION; RECOVERY.

(Under the care of Mr. E. DOWNES.)

In the month of August 1877, a young woman, aged about twenty-two, married, applied at the hospital. Her abdomen was very prominent, as if from pregnancy. It appeared, however, that she had never menstruated. Her abdomen was tense, and the tumour ascended nearly to the ensiform cartilage; it was oval and smooth, but not very movable. A vaginal examination was suggested and finally agreed to. The tumour was felt distinctly, and with one finger in the vagina and the other hand externally the tumour, which was quite hard, could be moved. There was no tenderness. What was believed to be the os uteri was also felt so open that the finger could easily have been pushed into it, but it was not thought wise to make any further examination until arrangements for operation were completed. There was no cervix uteri to be felt, and very little vagina, but the cervix had apparently been obliterated by the tumour. The canal which was taken to be the os uteri was close to the symphysis pubis.

A diagnosis was made of a fibrous tumour of the os uteri. The patient was told that she was suffering from a very serious disease which required an operation, but that the risk was great. Her suffering was so great that both she and her husband begged that something should be done.

She was admitted into hospital. Her treatment for about a week consisted merely in giving her perfect rest and small doses of opium to relieve the distress, paying attention to the bowels at the same time. Every day she begged for the operation. Another medical man saw the woman with Mr. Downes and examined her carefully externally and by the vagina, but did not use the sound.

After about ten days Dr. Ross, the civil surgeon, arrived in Srinagar; he and Dr. Williams of the Indian Medical Service were both present. The patient was put under chloroform, and then a thorough examination of the parts was made. She was placed in the lithotomy position and the parts exposed to view. It was found that what had before been taken for the os uteri was the meatus urinarius, which was enormously dilated, appar-

ently by having been used instead of the vagina in sexual intercourse; this became still more certain by passing a finger into the bladder. On looking carefully into the small space which represented the vagina a little white spot could be seen in the mucous membrane, surrounded by a less distinct whitish ring; this white spot apparently marked the position of the os uteri, but it was so completely closed that it could not be felt by the finger.

It was now evident that this was a case of complete congenital occlusion of the os uteri, and the enormous tumour, reaching nearly to the ensiform cartilage, was an accumulation of menstrual fluid. The point of a small conical cautery iron, heated nearly to redness, was pressed firmly in the position of the os uteri; the iron at once cut through the mucous membrane and the small amount of tissues beyond, which extended at the most only about a quarter of an inch, and sank into the uterine cavity, from which issued a thick fluid of a blackish-red color, perfectly opaque, and almost devoid of smell. Dr. Ross pressed on the fundus of the uterus, and after much of the contents had been discharged, a very distinct hour-glass contraction of the womb was noticed; gradually this gave way, and by gentle pressure on the fundus the whole contents of the uterus, about six pints were discharged. The last part consisted chiefly of clots and shreds, and were expelled by dilating the os with the finger. The uterus was well washed out with tepid water containing about 2 per cent. of carbolic acid. There was no hæmorrhage from the incision, and it was dressed with lint and carbolic oil. A firm bandage was applied round the abdomen, and a good pad placed over the uterus, which had contracted well.

The woman was placed in a room by herself, removed altogether from the other patients, and her husband undertook to nurse her. One of the dressers was ordered to change the dressings twice a day, and to introduce a large bougie into the new os uteri every morning; and ergot was ordered to be given internally. When she recovered from chloroform she had no pain, and expressed herself immensely relieved by the operation. For some days there was a considerable bloody discharge from the womb.

After the operation all went on well for three days; the temperature during that time was normal. On the fourth day she complained of a bad cough, and such great difficulty in breathing that she had to be propped up in bed. Her temperature was 105° F. Twenty grains of salicylic acid were given every hour. A dose was given at once, and the temperature fell a degree; after the second dose it fell to 101°, and after the third dose to 100°. After the second dose she expressed herself to be very much relieved, and said that she felt so hungry that she asked for food; after the third dose she felt rather nauseated, and the salicylic acid was ordered to be given only every four hours. Next day the temperature was normal, and the salicylic acid was stopped; the cough and dyspnoea remained troublesome. Nothing amiss could be detected with the stethoscope. A simple cough mixture was given. After exactly a week the temperature again rose to 105° in precisely the same way, and was as speedily reduced to normal by salicylic acid. It did not again rise while she remained in hospital, and the cough and dyspnoea gradually disappeared.

The rest of the story is soon told. A month after the operation she insisted on going home. She has not been heard of since. When she left the hospital she was much improved in every way; the discharge from the uterus had ceased; the os uteri was nearly natural in size and shape; the

vagina was longer than before, though still much shorter than it should have been; a cervix uteri could be distinctly felt in the vagina. Her general health was very much improved; she was fairly strong and in excellent spirits.

GREAT NORTHERN HOSPITAL.

TWO CASES OF GUNSHOT WOUND; REMARKS

(Under the care of Mr. SPENCER WATSON.)

For the following notes we are indebted to Mr. Wharry, house-surgeon.

A man having shot his wife, attempted his own life. On June 6th Robert C—, aged fifty-one, was admitted in the afternoon with four wounds on the right side of his scalp, all down to the bone. These had been caused by his discharging a revolver at himself. There was a good deal of hæmorrhage on admission, which was controlled by pressure. The wounds were enlarged, and search was made, but no bullets were discovered. Water-dressing was applied. The patient passed a restless night, and appeared next morning in a very depressed condition, continually lamenting over his condition, past and present. Pulse quiet; temperature not raised; he took his breakfast; wounds looking well. On the 9th he appeared more restless; the scalp was rather puffy around the wounds and discharging a little; poultices were applied; temperature 101°; pulse quiet. Next day he was in much the same condition, the temperature falling to 99·8°; wound discharging; complained of a good deal of pain in the head. On the 12th the temperature was 99°; wounds discharging freely; very restless. On the 13th in the evening the temperature was 104°; scalp more puffy; a bullet, very much flattened, was extracted from the wound over the forehead. On the 14th and next day there was slight improvement, the general condition being good; temperature 100°. On the 17th the temperature was in the night 104°. On the 19th the wounds were discharging freely; other conditions good; temperature 102°. On the 20th the temperature in the night was 103°; much pain in head; wounds discharging; slept well. On the 22nd the wound over the parietal bone was enlarged, and another bullet was discovered considerably flattened, and removed. On the 25th the patient was much better, and the wounds showed a disposition to heal.

The patient was discharged on July 15th, with the wounds quite healed. The man had apparently recovered from the effects of his injuries. During the whole of his stay in hospital he was given chloral and bromide of potassium every night.

Mrs. C— was admitted on the same day with a small circular wound, about an inch and a half behind the right ear, just over the apex of the mastoid bone, which was stained with gunpowder. The wound apparently extended in a downward direction into the soft parts of the neck. A search was made for, but no bullet discovered. The wound healed up under water-dressing in ten days, without any discomfort to the patient, beyond some slight stiffness of neck.

Remarks by Mr. SPENCER WATSON.—The slight amount of damage that can be inflicted by a saloon pistol, even discharged at close quarters and into a vital part, is well illustrated by these cases. The man who is said to have made the attempt on his wife's and his own life had been injured in a railway accident about six months before, and had ever since been much changed, his right arm and leg having been partially paralyzed. In spite of the solatium of substantial damages awarded him

by the court before whom the case was tried, he did not recover either mentally or physically, and when he attempted the acts alluded to he was no doubt under the influence of delusions. The wounds inflicted were very insignificant. All seven chambers of the revolver had been discharged, and two of the pellets were found on the spot. These were conical, and of the size of large peas. To test the penetrating power of the revolver, the police loaded and discharged it at a distance of five feet from a half-inch deal board. The bullet easily passed through. This weapon must have been discharged by C— at his wife when her back was towards him at about the distance of five feet, and the shot passed into her neck immediately behind the mastoid process. She had literally no symptoms referable to this injury, and three months after it was as well as ever, the pellet still remaining embedded somewhere in the muscles of the neck. In the case of C— there were very slight symptoms of surgical fever, which, however, soon passed off when the pellets were extracted.

WEST BROMWICH DISTRICT HOSPITAL.

CASE OF EARLY PERFORATION IN TYPHOID; REMARKS.

(Under the care of Mr. LANGLEY BROWNE.)

For the following notes we are indebted to Mr. F. F. German, resident medical officer:—

T. G—, aged eighteen years, presented himself in the out-patient department on the morning of September 27th. He had journeyed between two and three miles, having walked a considerable portion of it. He was suffering intense pain, which he referred to the region of the abdomen, the walls of which were flaccid; his face was vacant of expression, pulse weak; he walked with difficulty, and had been ill ten days. The bowels had been moved daily, but the evacuations were "frothy, sometimes streaked with blood." He was admitted to the wards and four minims of the official solution of morphia were injected hypodermically. This gave him great relief. Examination revealed nothing further; there was no increase of temperature, no other history than above obtainable, and the diagnosis was consequently a matter of some doubt. In the evening the pain referred to the whole surface of the abdomen again became very severe, and marked tympanites ensued. Between two and three ounces of clear high-colored urine, containing one-eighth albumen, were drawn off. The patient expressed relief, and subsequently conversed freely. About 9 p.m. he was observed to put a finger of each hand in his mouth, as though to widely extend it, and was writhing in great pain. This modified, but he rapidly sank, and died at 10:30 p.m. the same night.

Necropsy, the following afternoon.—In the thorax were extensive pleuritic adhesions on the left side, and the cavities of the heart were nearly empty. On opening into the abdomen a large quantity of chylous fluid escaped; the peritoneum was sticky and slightly adherent, and the small intestines were distended to nearly size of large. The ileum was much congested, and on its inner surface were several small typical ulcers, one of which, about three and a half feet from ileo-cæcal valve, perforated the bowel and was still patent. The other organs were healthy.

Remarks.—Perforation has been estimated to occur in from 1 to 2 per cent. of the entire number of sufferers from typhoid, and of the fatal cases has been variously stated to have occurred in from 8 to 12 per cent. As to the time of occurrence and situation of this accident, there are but few reliable

statistics. In those tabulated by Hoffmann, 9 per cent. only occurred at the end of the second week, while 27 per cent. happened between the eighteenth and twenty-first days, a similar number at the end of the fifth week, and the remainder subsequently. In 77 per cent. of these same cases, the perforation occurred at a spot not exceeding twenty inches above the ileo-cæcal valve, and in about 11 per cent. only at the same distance as in this case. I would add, that twelve days previously the boy had been at work, and during his illness, though at times in considerable pain, was not confined to bed. Was it the typhoidæ ambulans of some authors?

BEDFORD GENERAL INFIRMARY.

A FISH-HOOK IN THE OESOPHAGUS; EXTRACTION; RECOVERY.

(Under the care of Dr. GOLDSMITH.)

For the following notes we are indebted to Mr. E. A. Laurent, M.B., resident surgeon.

F. P—, aged ten, of Great Brickhill, Beds, whilst engaged in fishing held in his mouth a fish-hook attached to a piece of gut, and accidentally swallowed it. He was admitted to the infirmary eleven hours after the accident, under the care of Dr. Goldsmith, senior surgeon to the institution.

The only subjective symptom on admission was pain over the episternal notch. Half an inch of gut was seen protruding from his mouth, and on following the gut backwards with the finger, the notion conveyed to the touch was that the hook lay somewhere in the windpipe, but the boy had no cough, no dyspnoea, and his voice was perfectly clear. On applying gentle traction to the extremity of the gut, great resistance was felt. This was consequently discontinued and chloroform administered. A piece of silk ligature was tied to the end of the gut, and to the extremity of the silk a fine wire was attached. A traveller fourteen inches long was then passed along the twisted chain of iron wire, silk, and, lastly, gut down the oesophagus. It, however, proved to be too short to reach the hook; it was therefore withdrawn and a full-sized oesophageal bougie substituted for it. This passed with perfect ease until it reached the bend of the hook; here slight resistance was felt, which was easily overcome by pressure. During this part of the operation the bougie touched the cardiac end of the stomach and vomiting was induced, although the insensibility was nearly complete. The bougie was kept in position and the wire tightened; both bougie and hook fixed at its extremity were carefully withdrawn without any further trouble. The hook proved to be a No. 6 perch, and the gut was nine inches and a half long.

NORTH STAFFORDSHIRE INFIRMARY.

CASE OF PREGNANCY WITH RETROVERSION OF UTERUS, CAUSING RETENTION OF URINE (160 oz.); FATAL RESULT; REMARKS.

(Under the care of Mr. SPANTON.)

MARY ANN H—, aged thirty, married, was admitted into the infirmary on July 2nd, 1881, for supposed abdominal tumour. She stated that she had usually good health, and believed herself to be about four months pregnant, as menstruation had ceased for that length of time, and the areolæ of the breasts indicated it. For a fortnight before admission no urine had been passed. She complained of great pain in the hypogastrium, and

the abdomen was much enlarged, with dull percussion from the pubis to above the umbilicus, and extending to the iliac regions. The lips were dry, the tongue brown, and strength much exhausted. Frequent sickness both before and after admission. The legs and vulvæ were cedematous; bowels constipated. She had been under the care of a medical man previously. A catheter was at once passed and 160 ounces of urine drawn off, giving great relief. The following day 70 ounces were obtained, quite dark from admixture of blood and blood-clots. Considerable faintness followed this, and stimulants and astringents were freely administered.

On examination the body of the uterus was felt to occupy the whole of the posterior portion of the pelvis, pressing upon the rectum and neck of the bladder. The os uteri could not be felt; the uterus was enlarged to the size of about the fourth month of pregnancy. Mr. Spanton desired to attempt the reduction of the retroversion, but to this the patient would not then consent. A consultation of the staff was held, and the next day, chloroform being administered and about seventy ounces of bloody urine withdrawn from the bladder, Mr. Spanton passed his hand up to the uterus, the fundus of which felt like an enormous child's head, so that there was barely room for the hand to pass. The os uteri was high up behind the symphysis pubis, and the uterus appeared to be literally "upside-down." By continued steady pressure with the palm of the hand the uterus was felt gradually to rise into its normal position above the brim of the pelvis, and the cervix was then felt in the centre of the vagina. Once replaced, there seemed no tendency for the uterus to fall back, and on recovery from the anæsthetic the patient felt greatly relieved. In the evening fourteen ounces of urine mixed with blood were drawn by catheter, after some had been passed naturally. Signs of exhaustion with sickness continued, and the patient gradually sank and died at 11 A.M. on July 6th. No post-mortem examination was allowed.

Remarks.—The case is of interest as illustrating one of the grave dangers of neglected retroversion during pregnancy, and as showing to what an enormous extent the bladder may be dilated without actual rupture. The case was sent in as one of ovarian disease, and casually had the appearance of one; but the catheter quickly solved that doubt; and it was indeed unfortunate for the patient that such a simple measure was not employed earlier, as it is quite possible that the extreme distension of the bladder helped to exaggerate the retroverted condition of the uterus, which was, in its turn, originally the cause of the retention.

ESSEX AND COLCHESTER HOSPITAL.

UNUNITED FRACTURE OF OLECRANON; ENDS UNITED BY OPERATION; CURE.

(Under the care of Mr. LAVER.)

Charles C—, aged thirty, a mariner, was admitted on Oct. 27th, 1881, for ununited fracture of the olecranon. On examination the two portions of bone were found to be sufficiently apart to allow two fingers to be placed between them. This separation caused loss of power, and there was also some tenderness on pressure. The accident (a fall on the deck at sea) by which the fracture was produced occurred on August 13th, 1881. His arm was properly placed on a splint, but with the result above mentioned, and it was determined to try to unite the fragments, and for this purpose on November 4th an operation was performed under full antiseptic precautions. The bones were ex-

posed, scraped, drilled, and wired together with stout silver wire, the joint syringed out with carbolic water, and the arm placed on a front splint. On the 6th the limb was dressed; there was a slight stain of discharge, but no inflammation. On the 11th it was dressed again, and the stitches were removed. On the 20th it was dressed, and then there was no discharge. When dressed on the 25th there was no discharge, and the wound was healed.

On December 22nd, the wire in being removed snapped off and could not be taken out. The patient could move his arm freely without pain, and union had taken place, and he was discharged on leave of absence.

Jan. 2nd, 1882.—Patient returned, complaining of a pricking sensation; it was found to be caused by the broken wire, which was cut down upon and removed.

Feb. 6th.—Long extension splint, which had been on his arm, removed. On the 20th he was discharged cured, with perfect union and full power.

Remarks.—The case was kept a long time on the splint in consequence of the man's occupation, and the unfortunate accident of the wire breaking in further lengthened it.

Medical Societies.

PATHOLOGICAL SOCIETY OF LONDON.

Ulcer of Duodenum.—*Diaphragm deformed through Rickets.*—*Aneurism in Children.*—*Aneurism of Aorta and Abnormality of Heart.*—*Obturator Hernia.*—*Tricuspid Stenosis.*—*Parovarian and Broad Ligament Cysts.*—*Gangrene of Fingers.*—*Mediastinal Tumour.*—*Perforating Ulcer of Colon.*—*Cirrhosis of Liver.*

THE first meeting of the present session of the Pathological Society was held on Tuesday, Oct. 17th, S. Wilks, M.D., President, in the chair. There was a very full attendance of members. It was noteworthy that there were no "card-specimens" exhibited. The President prefaced the business of the evening by an appreciative reference to the late Dr. Peacock, one of the earliest members and a former President of the Society. Dr. Wilks said that during the recess the Society had lost one member to whom he felt compelled to make a passing reference. Dr. Peacock formed one of the small band that met many years ago to found the Society. He was one of its earliest and most valuable contributors, and at the last meeting but one he showed a specimen of malformation of the heart, a subject on which he had won a world-wide reputation. His career was a most enviable one; he was not ambitious as regards practice with its emoluments, and was thus able to devote himself with undivided attention to his hospital work, and in the autumn could travel and devote himself to science and literature. He had been a model member of the Society, and he could not allow that occasion to pass without a brief reference to one who for many years had been so closely connected with it.

Dr. Norman Moore showed several specimens. 1. A circular ulcer, as large as a fourpenny piece, situate in the duodenum, just outside the pylorus. Its base was adherent to the pancreas; and at one point the ulcer had penetrated a considerable branch of the pancreaticoduodenal artery. This perforation was the cause of death. Post mortem

the whole intestine was distended with blood, but there was none in the stomach. The patient was a man aged thirty-four years. His first symptom was a hæmatemesis of about a pint at 10 P.M. on May 9th. He came to St. Bartholomew's Hospital at 11 P.M., looking much blanched. After admission he vomited blood again at 2.30 A.M., and a second time, more copiously, at 6.30 A.M.; he became collapsed and died at 8 A.M., ten hours after his first sensation of illness. 2. A deep ulcer, in parts healed, also situated in the duodenum close to the pylorus. Its floor was partly formed by the adherent pancreas, and partly by peritoneum. The patient, a bricklayer, aged forty-nine years, had complained of a slight degree of pain after eating, for three months, but not to a sufficient degree to make him apply for treatment. He died of a severe pulmonary catarrh. 3. Enlarged Ribs of Rickets pressing upon the Liver through the Diaphragm. A cast of the under side of the diaphragm showed three large beads on the seventh, eighth, and ninth ribs. These pressed upon the diaphragm and through it upon the liver, causing well-marked depressions on each lobe. From a rickety child aged one year and eight months. 4. A drawing showing Depressions in the Liver due to Enlarged Ribs in another rickety child aged one year and seven months. These depressions perhaps appeared larger post mortem than they would during life, but certainly indicated a permanent pressure of the enlarged ribs upon the liver, a pressure increased by the fact that both children had constricted chests. He suggested that the slight thickenings sometimes observed in the capsule of the upper part of the liver in children and in adults might be due to the pressure of beaded ribs through the diaphragm. 5. An Aneurism of the External Iliac Artery, from a girl aged seven years. The aneurism was at the origin of the external iliac on the right side, and it was a dilatation of the vessel extending more to the inner than to the outer side. Its cavity was filled with firm laminated fibrin. A microscopic section showed that the aneurism was a simple dilatation of the vessel, all parts of which were represented in the wall. There was a marked increase of nuclei in the middle and deepest layer of the inner coat. No other aneurism was found. On the mitral valve there were some small growths, and on one aortic cusp there was a very large calcified growth. The aorta itself was free from any obvious morbid change, and a microscopic section showed it to be perfectly healthy. The girl had died suddenly. The aneurism would appear to have been due to an embolus from the aortic valves, followed by a deposit of fibrin, in the method of formation first suggested by Dr. John Ogle in the *Path. Soc. Trans.*, vol. viii., p. 168 (1857), and afterwards more fully treated of by him in a paper in the *Medical Times and Gazette* for Feb. 24th, 1866, and by Mr. Callender in the *Path. Soc. Trans.*, vol. ix., p. 93. 6. The Heart and Aorta of a girl aged five years, showing an aneurismal bulging a quarter of an inch above the Aortic Valves. The aneurism was due to an ulcer on the posterior wall of the aorta, which was associated with an ulcerative endocarditis of the aortic valves. There were also minute growths on the mitral and tricuspid valves. The child had acute general tuberculosis, and died with tubercular meningitis. 7. The heart and aorta from a man aged eighteen years, who died in St. Bartholomew's Hospital with Bright's disease and pericarditis. The right side of the heart and the mitral valve were normal. Just below the aortic valves was a thickened ring of fibrous tissue, attached on one side to the septum ventriculorum, and on the other to the outer wall of the heart. Above this ring the aortic valves were competent, and of nor-

mal form. It was suggested that this ring, which had a diameter of one-third of an inch, might be due to an imperfectly developed second tier of aortic valves, formed from the original endocardium, like the numerous rows of aortic valves in the ganoid fishes. At the root of the innominate artery there was a circular opening, one inch in diameter, which led into an aneurismal cavity partly filled with laminated fibrin. The contents of the sac had dissected between the layers of the pericardium, and formed a mass, two inches by two inches and a half, resting on the base of the heart, pressing upon the pericardial veins, and causing an enormous serous effusion which stretched the pericardium across the whole front of the chest. The patient had had an illness, which might have been acute rheumatism, nine years before his death. Most cases of malformation of the heart and aorta are due to either endocarditis or congenital variation. This example was interesting as illustrating a result of variation in its double row of structures around the aorta, and a result of acute endarteritis in its aneurism.—Dr. Payne said that Dr. N. Moore's last case reminded him of a case of his own. Some years ago he brought a heart to the Society which he then thought presented a rudimentary additional series of aortic valves. But a committee appointed to examine the specimen reported that they were not valves at all, but only thickenings of the endocardium; and he (Dr. Payne) was sure they were right; and he had since seen transitional forms of endocardial thickening.—Dr. Pye Smith asked if the fibrous ring was not rather to be ascribed to a persistence of the foetal constriction between the bulbous aortæ and the ventricle. This had been described, and he thought it more probable that Dr. Norman Moore's specimen was an example of it than of a reappearance of a structure for which they had to go so far back as to ganoid fishes.

Dr. S. Wilks said that aneurisms in children were very interesting; they had been clearly shown to be due to embolism. The aneurism was no doubt formed at the exact spot of the embolus and not above it, and it had been suggested that in cases of ulcerative endocarditis embola containing micrococci might cause an inflammatory softening of the artery. Older physicians, such as Addison, had recognized a connection between rheumatism and aneurism. He further asked whether Dr. Norman Moore knew of the cause of the duodenal ulcers.—Dr. Norman Moore said he did not know of any special cause. All the valves of the heart referred to by Dr. Payne were quite free from disease, and he thought it would be rash to ascribe the thickening to an endocarditis so severe as to cause this, but which did not implicate the aortic valves.

A committee consisting of Drs. Payne, Pye Smith, and Coupland was requested to examine the heart.

Mr. Bowlby showed two specimens of Obturator Hernia taken from a woman aged sixty-nine, married, mother of three children, very thin, with no history of abdominal obstruction. On June 4th she was suddenly taken with great pain in the abdomen; collapse, vomiting, and constipation; four days later she was admitted to St. Bartholomew's Hospital with distinct signs of intestinal obstruction. No distinct local tenderness could be made out; vaginal and rectal examinations gave no assistance. Two days later there was pain in the inner and back part of the thigh, which she said she had been subject to from chronic rheumatoid arthritis. She died on the eleventh day of her illness. At the autopsy there was found a strangulated hernia on the right side, and an empty hernial sac on the left side. The hernia on each side passed over the external obturator mus-

ale; on the right side the nerve and artery were stretched over the upper part of the sac. The right sac contained a coil of intestine adherent to the sac; there was no fluid in the sac. On the left side the sac was not so large as a walnut; on this side the obturator artery passed under the sac and divided into two beneath it, one division passing on each side of the sac. The patient was of the sex, age, and emaciated appearance common in cases of obturator hernia. The distribution of the arteries was important, but appeared to be various. In the last case at St. Bartholomew's Hospital, occurring thirty years ago, recorded by Mr. Stanley, the artery lay in front of the sac; in another specimen in St. Bartholomew's Museum the artery was on the inner side; the position of the nerve in front was constant. The intestine had been said to be drawn out into diverticula in cases of obturator hernia, but that was not so in this case. Double obturator hernia had been not rarely described, and the co-existence of other herniæ was not infrequent. In most of the cases the strangulation had not been very acute; in this case the gut was, even after eleven days, not gangrenous, nor very intensely congested. In one case the constriction lasted twenty-one days before death occurred. In Stanley's case, as in this, the gut was adherent to the sac. He thought the indication was, after diagnosing the case, to cut down and expose the hernial sac, and then to open the sac, divide its neck, and return the congested contents.

Dr. Bedford Fenwick showed a specimen of Tricuspid Stenosis from a woman aged thirty, who had rheumatic fever at fifteen, and afterwards suffered from winter cough and dyspnoea; she went on from bad to worse till admitted into the London Hospital under Dr. S. Fenwick; there was marked distension of jugular veins but no cyanosis, cardiac dullness very wide to the right, a well-marked pre-systolic apex thrill and pre-systolic and systolic apex murmurs; proceeding to the right another pre-systolic and systolic murmur was detected. At the post-mortem both auricles, but especially the right, were very much dilated, the ventricles small. The tricuspid and mitral valves were greatly thickened, shortened and agglutinated together, causing marked stenosis. All the organs were congested. The spleen was during life tender to pressure and pulsed. Cases of this kind were now known not to be very rare. Since his table of forty-six cases he had been able to collect twenty-three more cases, twenty of whom were females averaging in age 31.7 years. In every case the mitral valve had been more changed than the tricuspid, and in all cases the general health had been good; the great dilatation of the right auricle caused increase of cardiac dullness to the right, and afforded a means of diagnosis.

Dr. Norman Moore showed the heart of a man, aged twenty-two, with tricuspid Stenosis and Disease of Mitral and Aortic Valves; the right auricle was enormously dilated. He remarked that tricuspid stenosis was very often associated with pericarditis, and this prevents the diagnosis of distension of the right auricle. In this case the veins of the neck were not abnormal in any way. The loud systolic and presystolic murmur were loudest at the apex with a pre-systolic thrill at the same place. There was pericardial effusion. In seven out of fifteen cases at St. Bartholomew's tricuspid disease had been associated with pericarditis as if the valve were only affected by very severe endocarditis associated with pericarditis. Dr. Wilks asked if Dr. Fenwick thought that the tricuspid and mitral valves were affected simultaneously or successively. Dr. Fenwick said that in two or three cases it appeared clear that the mitral

disease was primary, and the tricuspid disease succeeded. In more than half the cases there was a well-marked history of rheumatism.

Mr. Alban Dolan exhibited some preparations showing the relations of Cysts in the Broad Ligaments, whilst still young and minute, to neighboring structures. A parovarium, with the posterior layer of broad ligament dissected away so as to expose its tubes, was demonstrated; Gaertner's duct appeared like a small nerve running a straight course towards the uterus. Cysts springing from the vertical tubes of the parovarium are multilocular, and bear papillary contents lined with epithelium, which may be ciliated, but is often made up of cubical cells not bearing cilia. The normal epithelial lining of the parovarian tubes is not invariably ciliated, and if so, often tends to degenerate into its original cubical form. The outer end of the horizontal tube of the parovarium generally bears a small cyst, the lining of which resembles endothelium. Between the parovarium and the Fallopian tube, small cysts, lined with endothelium, are very common. It is these, or the terminal cysts of the parovarium, that form the starting point of the so-called "parovarian cyst," which is thin-walled, unilocular, and filled with clear fluid, but no papillary growths. There is no evidence that any of these cysts spring from the Fallopian tube, the terminal "hydatis" of which never attains large proportions. The multilocular papillary cysts of the hilum of the ovary, and of the neighborhood of Gaertner's duct, are identical with those arising from the vertical tubes of the parovarium, all these structures containing relics of the Wolffian body, the source of cysts of this kind.

Mr. Hutchinson showed, as a living specimen, a man who had lost the ends of nearly all the digits of his hands. The gangrene was brought on from exposure to cold. He was at work on a snowy night, and afterwards the ends of his fingers inflamed and became gangrenous; they have never recovered, for on any change of temperature they swell and become oedematous. The toes were not affected. There was a threatening of gangrene of the ears. Before this occurred, on any exposure to cold his fingers would "die" very readily. It was a case of peculiar constitutional weakness of circulation with liability to gangrene, and differing from common cases of frostbite in the slight intensity of the cold causing the death of the parts—Dr. Wilks said he had a boy in the hospital last year with gangrene of fingers, ears, and toes, and hæmaturia. All had healed up. The hæmaturia pointed to some blood condition.

Dr. S. West showed a specimen of Mediastinal Tumour from a boy aged fifteen, who had been ill for only two months. For three weeks he had a swelling in front of the chest, with brassy cough and dyspnoea, and pain down the side of the chest, and inner side of the left arm. After a few days in hospital the swelling increased and appeared above the sternum. A needle was inserted, but nothing was obtained. A day before his death the left pulse was found unequal. He died in an attack of dyspnoea. At the autopsy the tumour was found to be very large and growing from the mediastinal glands, pressing upon and over the heart, flattening it down against the diaphragm. The vessels and nerves on the left side were quite embedded in the tumour, but were all free on the right side. The only secondary growths were in the kidneys, but the primary growths had extended down to both front and back of the heart, under the pericardium, without implicating the muscular tissue. The growth was a small round-celled sarcoma. The nerves in the tumour were found to be greatly thickened, owing to infiltration with tu-

mour tissue. The case was interesting on account of the age of the patient; out of fifty-five similar cases only five occurred between ten and twenty years of age. Dr. Douglas Powell had given the average age as twenty-four. The whole mass had also grown with extreme rapidity; the shortest time given by Walsh was three months and a half. He had never seen the nerves thus thickened; but Dr. Quain had recorded a case in which thickening was due, however, to inflammation, and not to infiltration of the tumour. Dr. S. West also showed two specimens of Perforating Ulcers of the Large Intestine from Typhoid Fever. In both cases the disease was of long duration, and in both there were cicatrices of typhoid ulcers in the ileum. In one the patient died suddenly, with signs of peritonitis, and after death a collection of puriform fluid was found in the pelvis, and a perforation of the lower end of the sigmoid flexure. In the other the liver and intestines were found matted together in the right hypochondrium, where a collection of pus was found, and a perforation of the colon at the junction of its ascending and transverse portions. In this case the fever ran a mild course throughout; but there was all along one symptom which he had always observed to be attended with a fatal termination to the case—a scarcely audible first sound of the heart.

Dr. Henegge Gibbes showed microscopical sections of a specimen of Cirrhosis of the Liver in a child of seven months, following congenital absence of the common bile duct. The case was under the care of Dr. Steel, of Abercavenny. A male infant, eighth child of healthy parents, born, December 3rd, 1881, first began to show symptoms of jaundice a few days after birth; was treated with castor oil in mild doses, afterwards with iridin in doses of two to three grains thrice daily. This seemed to have a slight effect on the stools and skin; other remedies had also been tried without any result. Nutrition was maintained tolerably well till the sixth month, when wasting and ascites set in, and the child died on the 10th of July. The liver was found to be hard and smooth, and weighed four ounces after hardening in spirit. No common duct could be found in connection with the duodenum. Under the microscope dense bunches of fibrous tissue were found between the lobules, in the interstices of which were the dilated bile ducts filled with bile. The cells in the lobules seemed broken down, and did not stain. This seemed to be a case of cirrhosis following on congenital absence of the common duct. The jaundice not appearing for the first few days might be explained by the small amount secreted at that early stage having filled the diverticula of the bile ducts. After these were fully distended jaundice would be set up.

The Society then adjourned.

CLINICAL SOCIETY OF LONDON.

Treatment of Phthisis by Residence at High Altitudes.— Excision of Cancer of the Tonsil.

THE first meeting of the present session of this Society was held on Friday, Oct. 13th, J. Lister, Esq., F.R.S., in the chair. The new volume of the Transactions was stated to be ready for distribution, which is a fact very creditable to the hon. secretaries. The President read the new rules in reference to the exhibition of living specimens. He also showed the form of diploma of hon. membership, and stated that most of the hon. members recently elected had expressed in warm

language their sense of the honor thus conferred upon them.

Dr. Theodore Williams communicated a case of Phthisis treated by Residence at High Altitudes, the patient having been exhibited at a former meeting of the Society. A medical man aged thirty had cough and expectoration of three years' standing, followed by hæmoptysis, wasting, elevation of temperature, and great prostration; and when seen by Dr. Williams in consultation with Dr. Vereker Benden, on Aug. 30th, 1881, he presented the physical signs of consolidation of the upper lobe of the left lung. After five months' residence at Davos, including a walking tour of seventeen days in the Engadine, during the whole of which period he took exercise largely, he gained a stone in weight, and found his strength and power of climbing greatly improved. On first arriving at Davos he had dyspnoea from the rarefaction of the air, but this passed off, and his respiratory powers became greater than previously. On his return, Dr. Williams found an increase in the cyrtometric and other chest measurements, especially in the upper regions of the thorax; and the physical signs denoted the development of emphysema around the old consolidation and hypertrophy of the healthy lung. Dr. Williams stated that while he ascribed the general improvement of the patient to the dry form of antiseptic atmosphere and the sun's powerful influence, he assigned the arrest of the tubercular changes to the local effects on the lungs of breathing rarefied air, which by inducing emphysema caused an expansion of the thorax, at the same time opposing a barrier to the emeroachment of further infective processes in these organs. With regard to the durability of the good results of mountain climates, Dr. Williams's experience was that in well-selected cases one or two winters sufficed to produce permanent arrest of consumptive disease, though in many instances a prolonged stay of at least two years was desirable. Dr. Williams exhibited cyrtometric tracings of similar cases that had resided at Davos and Colorado for several months to illustrate the widening of the chest through breathing mountain air.—Dr. Althaus was much interested in this subject, as he had recently sent a case of advanced phthisis to Colorado, and the improvement that had followed was most marked. The patient referred to was a young lady with a cavity in one lung, hectic, and great wasting. All European climates had proved ineffectual; but after being at Colorado (8,000 feet above the sea) a week, there was a marked change in her state, and she was able to be out in the open air all day long. Patients were able to stay in Colorado all the year round; the weather was so fine that there was no need to send them into the lower levels at any time; the air was extremely dry. A residence of two years was considered desirable by Drs. Solly and Norman, who resided there, and with whom he had been in correspondence on the subject.—Dr. Broadbent could not quite see the point of the paper. Such a case as that related was not an infrequent experience, and the change noted was such as was often observed after residence in any of the usual winter resorts. He wanted to know whether in a large number of cases the results were better from residence at high altitudes than from residence in the south of France or Egypt.—Dr. MacLagan asked how far the arrest of the disease was due to residence in a germless atmosphere, such as was known to exist in such high altitudes, and how far to the general healthiness of the life at Davos. How far also was the enlargement of the chest peculiar to cure of a case of phthisis, or common to anyone moving to such a latitude.—Mr. Lister said that Dr. Williams's case was an example of improvement under many

favorable conditions. If high altitudes were useful, it was important to know how the good effects were brought about. If the air was germless or aseptic, he failed to see how that circumstance could interfere with the organizations already present in the lung. Possibly the absence of dust in the air might be one cause of the beneficial result. He had recently himself experienced in high altitudes an unsatisfied desire for taking deep inspirations, and this must after a time cause enlargement of the chest. But he asked whether there was any benefit in this; the deeper breaths were merely efforts to take in the same amount of oxygen as in lower altitudes. But how far was this desirable? If this remained permanent, on returning to the lower levels of course it would be useful. Residence in these high altitudes certainly did exercise a beneficial influence.—Dr. Wilberforce Smith remarked that a very small gain of flesh makes a great difference in the measurement of the chest. He suggested that an aseptic atmosphere might prevent the intercurrent inflammatory attacks which increase the phthisical state.—Dr. Williams, in reply, referred to his paper in the International Congress Transactions. In reply to Dr. Broadbent, he said that as a specialty of mountain climate he found he got expansion of the chest and change in the percussion note from dulness to resonance to hyper-resonance. In this respect this treatment differed in its effects from sea voyages, or residence in Egypt or the Cape. He was not himself sure that the air at Davos was germless; the air had never been analyzed. He thought the expansion of the chest was a distinct advantage; he also suggested that in these patients the lungs were often not fully developed, and residence at these high altitudes caused an enormous development of the lung. Almost all the natives of high regions have large lungs. He did not think Davos and such places were very successful in staying off intercurrent inflammations.

Mr. Golding Bird detailed a case in which he had removed an Epitheliomatous Tonsil in the manner adopted by Cheever (1871), and referred to three other cases of the same disease in which he had determined not to operate. The operation consisted in an external incision from the ear to the hyoid bone, through which the wall of the pharynx was reached with the greatest ease, and the tonsil with the adjacent pharyngeal tissue removed with the galvanic cautery. The later stages of the operation were aided by an additional incision through the cheek from the angle of the mouth. The disease having also affected the tongue, part of that organ was removed as well as an enlarged gland at the angle of the jaw. Until the wound closed an oesophagus tube was used for feeding, and though great relief was given to the patient, yet he soon succumbed to recurrence, not in the site of the excised organ, but in the tongue and in the lymphatics of the neck. The conclusions arrived at by the author were that where only a limited infection of the lymphatic glands existed, and where the faucial growth was circumscribed, or nearly so, operation was called for; but that in other cases feeding with tubes with subsequently gastrostomy was the treatment. The operation was itself far easier than many of daily occurrence, and seemed to offer no special risk to the patient. Of the four cases mentioned it was considered by Mr. Golding Bird that the disease was primary in the tonsil in three, in all four it was the left side that suffered.

Mr. Clement Lucas related a case of Excision of the Base of the Tongue, Right Tonsil, and part of the Left Palate for Epithelioma. The patient, aged sixty-four, a coalporter on the river-side, who had drunk freely, first came under Mr. Lucas's

care in Guy's Hospital on Feb. 13th, 1880. He was at that time suffering from a large aneurism of the right popliteal artery, causing pain and oedema of the leg and foot, and from a smaller aneurism of the left popliteal. Digital compression of the right femoral artery was commenced on Feb. 17th, and continued for sixteen hours, when the aneurism appeared to have consolidated, and pulsation could no longer be detected. On the following day some pulsation was re-established, and on the 20th digital compression was again commenced and continued for eleven and a half hours, when pulsation ceased and did not recur, the tumour afterwards gradually shrinking. An attempt was made about a fortnight later to cure the small aneurism in the left popliteal space by digital compression, but this failed, and as the tumour caused him little inconvenience, no further treatment was suggested, and he left the hospital. He was readmitted on August 2nd, 1881, suffering from epithelioma of the base of the tongue and right tonsil. On the right side of the tongue, opposite the last molar teeth, was a small ulcer, grey in color, and irregular on the surface. The ulceration extended along the anterior pillar of the fauces, and involved the right tonsil as well as the tissue between the tongue and the jaw. The surface of the tongue near the base was raised and indurated for about half an inch from the margin of the ulcer. The movements of his tongue were interfered with, so that mastication and deglutition were painful, and there was an increase of salivary secretion. No enlarged glands were felt beneath or behind the jaw. The operation was performed on August 9th. The patient being placed under the influence of chloroform, the cheek was first divided by an incision from the angle of the mouth to the masseter muscle, and the facial artery was twisted. A gag was then inserted on the left side of the mouth whilst the tongue was drawn forward with forceps, and the flaps of the cheek were held back by retractors. The back of the tongue and tonsil were in this way easily reached. The soft palate was next divided near the middle line by means of Paquelin's cautery, and dissected down with the anterior pillar and the tonsil. Attention was now paid to the tongue, which was divided in the median line with a scalpel, and carefully dissected outwards till the lingual artery was reached. This was seized with two pairs of torsion forceps, divided between, and the ends twisted without loss of blood. The tissue between the tongue and jaw was next dissected up, the cautery being used to stop any bleeding points, and finally the growth, with the base of the tongue, right tonsil, and half the soft palate, was removed in one mass. The cheek was brought to ether with three harelip-pins, and it united primarily. The patient recovered rapidly after the operation, and sixteen days later was again subjected to digital compression for the cure of the left popliteal aneurism, which was about the size of a pigeon's egg. Pressure was kept up with the aid of opium for forty-eight hours, but soon after this, though much consolidated, the tumour still pulsated. He left the hospital, with the tongue quite healed, on September 16th. He was readmitted into the hospital on February 13th, 1882. There was no return of the disease in the tongue or palate, which were united by a firm and sound cicatrix. There was a large mass on the right side of his neck below and behind the jaw, which commenced six weeks before, and grew rapidly, extending outwards beneath the sternomastoid. An operation for the removal of this growth was undertaken on the following day. A vertical incision about four inches in length was made, commencing behind the jaw, and the growth dissected round. It was found necessary after-

wards to enlarge the wound transversely. In the course of the operation the lower part of the parotid gland, a portion of the sterno-mastoid, the posterior belly of the digastric and stylo-hyoid, and a portion of the submaxillary gland were removed, all of which were infiltrated. The facial artery was twisted and the facial and lingual veins ligatured with catgut. At the bottom of the wound the internal jugular vein and the two carotids, with the hypoglossal nerve, were exposed. Two enlarged glands were also removed from beneath the sterno-mastoid. The patient recovered without a bad symptom, and left the hospital on March 24th. He was again seen in July last with a recurrence of the growth on both sides of the neck, but there was still no sign of disease in the original site. It was not then thought advisable to interfere further. Mr. Lucas said that, by the operation described, it was evident a cancerous tonsil, with the adjacent structures, can be completely removed from within the mouth, and when this was practicable, it had the advantage over the external operation of avoiding the fistulous track, through which saliva was apt to ooze. For the rest, the treatment of cancer here did not differ from the treatment of it elsewhere. The treatment—and the only treatment—was to operate early, and to operate late; to operate, indeed, so long as it was possible to remove a loathsome outgrowth without great immediate danger; to operate to keep it local; to operate on the earliest return; and though we might often be disappointed in our attempts to eradicate the disease, we might still prolong life, or, as in the case before us, succeed in driving the disease from its original site to one where it was less offensive, and more easy for the patient to bear.

Mr. C. Heath congratulated Mr. Golding Bird and Mr. Lucas on their bold procedure. Dr. Cheever's operation must of necessity be of great difficulty, but was successful in his and Mr. Golding Bird's hands. But the question arose as to whether good was done by such an operation. His own view was that, whenever the surgeon can get beyond the cancerous disease, an operation was justifiable, even when the growth was in the lymphatic gland; but the opinion was often given by eminent surgeons that cancerous disease of lymphatic glands was a bar to operation. He should therefore be glad to know what the general opinion was.—Mr. Morratt Baker thought that Mr. Lucas was very successful in the long period that elapsed without local recurrence. He asked if the part was removed with the *écraseur*, or with the scissors, after Mr. Whitehead's method. He had himself used in many cases the *écraseur*, to prevent hæmorrhage and lessen pain. He quite concurred with Mr. Heath in advocating the removal of cancerous lymphatic glands where they could be completely removed.—Mr. Butlin thought removal of the tonsil through a deep wound on the neck was hardly worth doing, although possibly justifiable. Cheever had had two cases, and Czermak had had one, but in all there was rapid recurrence. As a result of his researches, he found that the only case of malignant disease of the tonsil really improved by operation was one of lympho-sarcoma, removed through the mouth, in which there was freedom from recurrence for two years at least: and he rather doubted whether there was not some error in the diagnosis in this case, as it was extremely difficult to distinguish a lympho-sarcoma from an ordinary enlargement of the tonsil.—Mr. Lister said there was no doubt of the boldness and skill of the operators in the cases related. But he feared that, on the average, operative interference was more likely to be harmful than beneficial. Mr. Lucas's case was very successful and favorable. He asked for a more detailed account of the last

step of this operation. He was glad to know that surgeons now generally removed cancerous lymphatic glands when accessible; this was quite a change since he was a student. He believed he was the first person to clear out an axilla in cases of scirrhus of the mamma, and he had had reason to be very well pleased with his results. In a case of epithelioma of the lip and a single enlarged gland under the chin Mr. Syme used to operate, and with good results, although at the time he deprecated such operations where glands were affected in other situations.—Mr. Golding Bird's opinion was distinctly in favor of not operating in cases of cancer of the tonsil.—Mr. Clement Lucas said that in his case the tongue was divided entirely with the knife. The soft palate and tonsil were first dissected down, then the tongue was dissected up, and the mass to be removed was carefully divided, and any bleeding point was touched with a Paquelin's cautery. He thought his case showed that such operations were not hopeless, for he had freed the man from the loathsome disease in the mouth, and he was now suffering from a far more tolerable affection in the neck. The Society then adjourned.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Dislocation of the Foot, with Version and Torsion of the Astragalus.—Ophthalmoplegia Externa, complicating Graves's Disease.

THE first meeting of this Society after the vacation took place on the 24th inst., Mr. John Marshall, F.R.S., President, in the chair. At the commencement of the business of the evening, the President directed the attention of the Fellows present to certain proposed alterations in procedure initiated by the Council, comprising increased facilities for the discussion and reading of papers, the insertion of debates in the Proceedings, and the exhibition at the meetings of scientific inventions, anatomical and pathological preparations, etc.

Mr. Richard Barwell read a paper on Dislocation of the Foot with Version and Torsion of the Astragalus, of which the following is an abstract. Dislocation of the astragalus is not uncommon, the bone, displaced from the socket formed by the leg-bones as well as from the rest of the tarsus, receiving, in nearly all instances, a twist, so that its surfaces look in abnormal directions. Another very rare form of injury is that of which the following is an example: G. F—, aged twenty-eight, received the injury by the overturning of a gig that he was driving, he falling on the right foot. The foot was greatly inverted, the heel raised; the inner malleolus was much obscured, the outer very prominent. The round head of the astragalus was in front of and below the external malleolus. Running from the head to the upper part of that malleolus was a ridge of bone convex outward. A small wound a little way up the leg communicated with the seat of injury. Attempts at reduction, even though the Achilles tendon was divided, were ineffectual. Mr. Barwell excised the astragalus. It was in its normal place in the tibio-peroneal socket, but was twisted, so that the trochlea looked outward, and rested against the articulating face of the outer malleolus. The man did extremely well; he was discharged in three months, walking with crutches, and was shown at the Society's meeting, walking well without any assistance from crutch or stick. After a few remarks on the difficulty of nomenclature in disloca-

tion about the tarsus, the author referred to Malgaigne's description of version and torsion "*sur place*," the former referring to a turn of the astragalus on its perpendicular axis. Of these Malgaigne gives four examples, and the author had collected two others. They all, with one exception, were inward. Torsion, by which he means a twist on the antero-posterior aspect, is in reality more rare, although it would appear on first sight more common because Malgaigne quotes six cases; but on examination of the original records, these changes he found to be not *sur place* save in one case, Dupuytren's—and even here the bone was nearly extruded—and one preparation, the history of which is unknown, and in which the turn is very slight. The author's case is the only one in which a diagnosis has been arrived at during life, and, as far as can be ascertained, the only one in which the bone turned a quarter of the circle, and lay fairly in the tibio-peroneal socket. An appendix was added giving a short description of every case both of torsion and version in corroboration of these statements.—Mr. Spencer Watson, after remarking upon the rarity of dislocations of the astragalus, referred to the case of a girl who sustained a compound dislocation of the bone outwards, necessitating its excision. The result of the operation was very satisfactory, for having seen the patient a few years afterwards he found that there was free movement at the ankle and a normal appearance of the foot. Such a result was encouraging for the ultimate issue of Mr. Barwell's case.—Mr. Barwell explained the grounds upon which he arrived at a diagnosis in his case—viz., the projection outwards of the convexity of the trochlear surface of the astragalus. He exhibited a preparation of a foot after excision of the astragalus, showing bony union of the os calcis, scaphoid, and tibia—and believed this always took place—the subsequent mobility occurring at the tarsal joints in these cases, and not at the ankle. He referred to the fact that Malgaigne had misread some of the descriptions of astragalus dislocation, and stated that he excised the bone in preference to attempting its reduction, because it was detached from all sources of its nutrient supply.—The President confirmed Mr. Barwell's statement as to the discrepancies arising from imperfect descriptions of such injuries, and pointed out that the astragalus differs from all the other tarsal bones in having no tendon inserted into it. Its main connection was with the broad astragalo-calcaneal ligament, which must be torn through in the dislocation, thus seriously damaging the vitality of the bone, and leaving the surgeon no alternative but its speedy removal.

Dr. Francis Warner then read a paper on Ophthalmoplegia Externa complicating a case of Graves's Disease. The patient was a woman twenty-five years of age, and was the subject of Graves's disease of four years' standing. There was marked mental excitability, and she was frequently attacked with gastric crises, vomiting, dyspnoea, and palpitation. Both eyes were nearly immobile, a condition not accounted for by proptosis; this had existed five months before admission into hospital. Limitation of movements was not equal in the two eyes, and was greater in the horizontal than in the vertical directions; double proptosis was marked. There was also bilateral paresis of the seventh and fifth pairs of nerves, and marked tremor of the legs. There appeared to be no evidence of syphilis. Under treatment the goitre subsided, and the general condition greatly improved, but the ophthalmoplegia remains. The unequal amount of paralysis of the two eyes is taken as some evidence of an independent nerve-centre for the movements of either eye, and this

is supported by observations in infants in deep sleep and adults in coma, when either eye may be seen to move separately and independently. Again, the greater limitation of movement in the horizontal as compared with the vertical direction is pointed out as probable evidence that separate centres govern these movements respectively.—Mr. Power pointed out the reasons in favor of regarding Graves's disease as dependant on lesion of the cervical sympathetic, especially the cardiac and the gastro-intestinal derangements. In Dr. Warner's case the protrusion of the eyeball alone was not sufficient to account for its impaired movements, and there was evidently independent oculo-motor paralysis. Corneal ulceration was very rare in Graves's disease, and he attributed it in this case to inability to move the eyeball upwards beneath the lids. In this case there were evidently cerebral lesions superadded to those of Graves's disease.—Dr. Althaus had never met with the association of Graves's disease and ophthalmoplegia. Although the symptoms of Graves's disease point to lesion of the cervical sympathetic, yet in many carefully recorded cases no such lesion had been found. Syphilis was the almost invariable cause of ophthalmoplegia, whether internal or external. Speaking of Mr. Hutchinson's view as to the localization of lesion of the lenticular ganglion in internal ophthalmoplegia, and of the nucleus of the third nerve in the aqueduct of Sylvius in external oculo-motor paralysis. Dr. Althaus remarked that recent observations (pathological and experimental) in Germany pointed to the existence of centres governing the iris and ciliary muscle in close proximity to the third nerve nucleus. Again syphilitic lesions were often wide-spread (e.g., ophthalmoplegia might complicate locomotor ataxy) and it was conceivable that both the centre mentioned and the cervical sympathetic were involved in this case. He also referred to the persistence of ophthalmoplegia and its intractability, as well as liability to relapse, although some amelioration may be produced by large doses of iodide of potassium.—Dr. Savage had seen many cases of Graves's disease in the insane, but never associated with ophthalmoplegia. In two cases examined post mortem he had failed to find any lesion of the sympathetic; but in one there was disorganization of the suprarenal bodies. Although Graves's disease was a nervous disease, it exhibited three or four different conditions, and was met with in general paralysis of the insane as well as with other derangements.—Dr. B. O'Connor said that in some of Graves's earlier cases the thyroid enlargement was temporary, and in one case a peculiar form of dyspnoea was attributed to temporary dilatation of the aorta pressing on the trachea. He suggested that the cardiac ganglia might be the seat of lesion. In later cases described by Graves, the goitre was more permanent, and a marked difference was observed between the carotid and radial pulse.—Dr. Warner, in reply, pointed out the large area involved in this patient, there being paralysis of the fifth and seventh nerves as well as of the third, and the tremor of the feet indicated some change in the spinal cord. There was no evidence at all of syphilis; and the corneal ulcer was purely local, and probably due to the lesion of the fifth nerve. Mercurial treatment has been tried but abandoned; and the diminution in the thyroid swelling followed the application of cold by Leiter's tubes. This improvement under cold suggested sympathetic disorder, the ophthalmoplegia remaining.

At the close of the meeting the President directed attention to two scientific instruments upon the table. One was an apparatus designed by Mr. Robson, of Leeds, for the purpose of producing a

dry antiseptic vapor. It consisted of two metal U-shaped tubes in connection with a foot-bellows, one tube being filled with cotton wool to filter the air, and the other with pumice to receive the antiseptic fluid—e.g., eucalyptol. The apparatus had been used in cases of ovariectomy, and it was intended to replace the spray. The other instrument was the ingenious metallic clinical thermometer originally shown to the Medical Congress last year by Messrs. Mayer and Melzer, who had since perfected it. It is constructed on the principle of a Bourdon tube, which is filled with a highly expansive fluid, and which in expanding moves a pointer set on a dial by means of a rack and pinion.

OPHTHALMOLOGICAL SOCIETY OF THE UNITED KINGDOM.

Chronic Membranous Inflammation of Conjunctiva.—Chronic Tubercle of the Choroid and Brain.—Military Tubercle of the Choroid and Lung without Meningitis.—Large Tubercle growing near the Optic Disc.—Destructive Ophthalmitis in Children.

THIS Society met for the first time this session on Oct. 12th, Mr. W. Bowman, F.R.S., President, in the chair. The President laid on the table a copy of the Society's Transactions, vol. ii.

Mr. Anderson Critchett and Mr. Juler showed a case of Rare Affection of the Conjunctiva, which they considered to be one of chronic membranous or so-called "diphtheritic" conjunctivitis. The patient was a young woman aged seventeen. Ten months ago she had local suppurating (soft) sores on the vulva anus, for which she was treated at the Lock Hospital. There were no symptoms of constitutional syphilis. No mercury was given, and she was discharged cured in two months. Five months ago she had an attack of what appeared to be inflammation of the ocular conjunctiva in both eyes. This was treated first with alum and then with zinc lotions, and was almost cured when a white patch appeared in the left eye near the lower cul-de-sac. It was a white, opaque, non-vascular, diphtheritic-looking growth, unattended by pain and without suppuration. Since that time it has gradually extended and now appears as a dirty-white shreddy mass, seated on a semi-indurated vascular base of the conjunctiva. The lower part of the ocular conjunctiva, the lower cul-de-sac, and the inner surface of the lower lid are the parts now attacked. Ten days ago the right eye became similarly affected, a white patch appearing in the lower part of the ocular conjunctiva surrounded by vascular injection. It is now (10th day) about 1.5 centimetres in length and 0.5 centimetres in width, situated horizontally between the cornea and the lower cul-de-sac. The cornea is clear and the vision normal. There is no suppuration and only slight pain and photophobia; iodoform lotion, quinine lotion, etc., have been applied, and mercury given internally without any improvement.—Mr. Power remembered a similar case in a man thirty years old who had a growth at the lower part of the outer conjunctiva. The growth increased, and eventually projected as a horny mass from the surface of the cornea. The eye was excised.—Mr. Nettleship saw about two years ago a girl with a patch of adherent membrane on an infiltrated base on the ocular conjunctiva, which had lasted about six or seven weeks when she was first seen. There was no surrounding inflammation, and he regarded it as a localized chronic diphtheritic patch. He touched it with lapis divinus several times, and it disappeared, leaving a scar. Other cases of chronic

diphtheritic conjunctivitis had been published, one by Dr. Businelli, of Rome, where masses of membrane kept reforming and protruding between the lids. Another case is recorded by Mr. Mason, of Bath, and others by Mr. Hulme and Mr. Hutchinson. It, therefore, seemed as if in certain cases diphtheritic conjunctivitis tended to become chronic.—Mr. Power added that in his case there was a distinct specific history.

Dr. S. West showed a case of Leucocythæmia with Retinal Changes (dilated veins, etc.)

Dr. S. Mackenzie read notes of a case of Chronic Tubercle of the Choroid and Brain. The disease occurred in a girl aged fourteen. There was no tubercular history. She had never been well since she had whooping-cough, eighteen months before her death, suffering from frontal headache, feverish attacks, diarrhoea, and occasional vomiting, and loss of appetite and flesh. Following this was white swelling of the right knee. She then rapidly lost sight, whilst the other symptoms continued. When first observed she was flushed and feverish; there was no abnormal signs in chest or abdomen. She was quite blind. Ophthalmoscopic examination showed double papillitis. In the left eye there was a patch of choroidal disease, larger than the disc, to the outside of it. It was opaque and yellow in the centre, with a zone of black pigment, and an outer margin of pigment. A smaller circular patch was below the disc, over which coursed retinal vessels. One small patch existed in the right eye. The diagnosis was chronic tubercle of choroid and brain. Later acute cerebral symptoms made their appearance, with high temperature, and terminating in death; these were thought to indicate acute tubercular meningitis. The head only was allowed to be examined at the necropsy, when acute tubercular meningitis, with several caseous tumours in various parts of the brain, were found. Microscopic examination of them showed aggregated tubercle with giant cells. The choroid was thickened owing to the presence of tubercles with giant cells. The retina was swollen, and the optic nerve and its sheath showed marked signs of inflammation. The brain tumours and tubercular choroid were examined for bacilli by the processes of Ehrlich and Heneage Gibbs with negative results. It was remarked that the detection of the tubercular disease in the choroid was of some value in aiding the diagnosis as to the nature of a coexisting encephalic lesion; but, unfortunately, owing to the kind of disease, this knowledge was of little service in treatment. That some intracranial disease was present was indicated by the double papillitis, headache, occasional vomiting, drowsiness, etc., and that it was tubercular by the age of the patient, the feverish attacks, the diarrhoea, wasting, and white swelling. Allusion was made to Deutschmann's inoculation experiments in rabbits, in which it was shown that the tuberculosis induced in the membranes and brain was followed by double papillitis and tubercle of the vitreous and choroid, and that the process was traced in post-mortem examinations to metastatic infection along the optic nerve sheaths. Deutschmann has also recorded a case of tubercular meningitis in a child in which an appearance of tubercle in the optic nerve sheath was present. The present case lent no support to this connection between the tuberculosis of brain and eye. Attention was drawn to the similarity of the changes in the eye and brain in showing us pathological processes as well as aiding in diagnosis.

Dr. Warner read notes of a case of General Military Tuberculosis; tubercle in choroid; no meningitis. The patient was a girl nine years of age. She presented continued fever and emaciation; respiration was increased in frequency out of pro-

portion to the pulse and temperature; this averaged 102° to 103° . There were crepitations over the lungs, but no signs of pneumonia. The optic discs appeared healthy, but in either eye there were three or four light-colored raised cloudy spots, at some points turning aside a retinal vessel. The child died eight days after these tubercles were first seen. At the post-mortem the lungs were found crowded with tubercles; others were found in the liver, spleen, and kidneys. There was no meningitis. The back of either eyeball being removed, tubercles were found in the choroid. The case was put forward as an illustration of the association of tubercles in the choroids as a part of the general miliary tuberculosis without meningitis.

Dr. Brailey communicated a case where a Tuberculous Mass, apparently primary, springing from the optic disc and immediately surrounding the choroid, simulated in some of its clinical features a glioma. The globe was enlarged and its tension increased; the cornea was increased in size, and the anterior chamber was deepened; the retina was detached except from the ora serrata; and it was this membrane that was visible during life, with its vessels, through the clear lens. There were many point-like posterior synechiae. Though the mass, which presented all the histological evidences of tubercle, replaced the tissue of the papilla, it did not extend backward beyond the lamina cribrosa, nor laterally for any distance in the choroid. As there was no precise microscopical evidence that it had originated in the retina or tissue of the papilla, the author presumed that a choroidal origin was the most likely in view of the number of cases of tubercular choroidal disease that had been described. The patient, a boy aged two, the second child, was stout and well, but had been within a few months very thin and weak. The eldest was four years of age. Before this there had been a miscarriage at four months. The mother died of consumption six months before the excision. The father was said to be healthy. The after history of the patient could not be traced.

Dr. Baxter said that during the last twelve years he had examined the eyes in a very large number of cases of tubercular meningitis, and in no instance did he find tubercle of the choroid, although optic papillitis was often found. In the only two cases which he had seen it was associated with very abundant tuberculosis in other organs.—Dr. Coupland said that although meningitis was present in every case in which he had found choroidal tubercle (about six in all), yet in these cases the tuberculosis was more or less general. The eyes, however, were seldom examined post mortem, except in cases of cerebral disease, and Cohnheim's statement as to the frequency with which choroidal tubercle occurred in subjects of tubercular phthisis apart from meningeal tubercle had never been contested.—Dr. Sharkey during a period of three years and a half had examined every case of tubercular meningitis at St. Thomas's Hospital, and had only once found choroidal tubercle, which was confirmed on post mortem examination. No case of tuberculosis was examined that did not present cerebral symptoms.—Dr. Barlow thought it was premature to make any general assertion as to the infrequency with which choroidal tubercle and tubercular meningitis coexist; and that the absence of choroidal tubercle in any given case of tubercular meningitis ought not to be assumed on ophthalmoscopic evidence alone without an examination of the back of the eye post mortem. He had seen about twenty cases of choroidal tubercle post mortem, and of these a large number were associated with miliary tubercle in the pia mater. He had notes of thirteen in which there was this coex-

istence, and believed there were more. A very fine dappled appearance of parts of the fundus is sometimes seen with the ophthalmoscope in cases of tubercular meningitis, and in two such cases he had found post mortem that it corresponded with some very minute tubercular spots associated with ordinary nodules of miliary choroidal tubercle. He thought that to such a lesion might perhaps be applied the term "tubercular dust," which was used by Barthé and Billiet in regard to a form of tubercle seen sometimes in the liver. In regard to Dr. Mackenzie's case, Dr. Barlow thought it was of importance as bringing before us the possible chronicity of choroidal tubercle. Dr. Barlow had had under his own care, about four years ago, a boy with a diffuse general massive infiltration of one choroid, which proved, on microscopic examination by Mr. Nettleship, to be indistinguishable from caseous tubercle. The eyeball was removed, and thirteen months afterwards, when the boy died, several tumours of caseous tubercle were found in the brain. Thus it would appear that in the choroid, as in other organs, several forms of tubercular deposit might be found, and possibly the one to which he had referred might be compared with a mass of caseous pneumonia in the lungs.—Dr. Sansom raised the question of the prognostic value of the detection of choroidal tubercle, which he had met with not only in cases of meningitis, but also in cases of ordinary phthisis. But on one occasion he was led to give a most unfavorable prognosis in a case of meningitis from finding in the fundus what seemed to him an unmistakable tubercle of the choroid. He subsequently learnt that the patient recovered, and this fact had shaken his confidence in the importance of choroidal tubercle in prognosis.—Mr. Hulke had for some years past examined the eyes in cases of meningitis, and could confirm Dr. Baxter's statement that optic papillitis was often met with, but choroidal tubercle (except as part of general tuberculosis) very seldom.—Mr. B. Carter remarked that several years ago he had opportunities of examining ophthalmoscopically a large number of cases of meningitis. Like Mr. Hulke, he met with in some cases a swelling or inflammation of the disc, and in cases too when the diagnosis was otherwise doubtful, but he never met with anything that he took to be choroidal tubercle. From his subsequent hospital experience he had met with choroidal tubercle in cases of general tuberculosis, but not in meningitis; he had also seen appearances simulating tubercle, and he thought its ophthalmoscopic diagnosis rested on an insecure basis.

Mr. Nettleship read a paper on Certain Cases of Destructive Ophthalmitis in Children. The chief object of the paper was to draw attention to the cases of deep-seated disease which more or less simulate glioma of the retina in their clinical features. The author believed that there were two principle types of morbid change in this class of cases—(1) irido-choroiditis, either acute and almost purulent or chronic, the result of either form being inflammation and opacity in the vitreous, with subsequent detachment of the retina and backward displacement of the ciliary processes by shrinking of the inflammatory material; hæmorrhage between choroid and retina might occur; (2) inflammation and condensation of the vitreous, especially in its outer layers, and in some cases also in its antero-posterior axis, probably the result of a chronic severe retinitis, no detachment of retina occurring. Iritis occurred in nearly all cases of "pseudo-glioma," and there was often severe inflammation of the eye in the early period of the case. It was particularly as to the causes of these eye changes that information

was wanted. It was not sufficiently known that the conditions called pseudo-glioma, whether following severe inflammation of the eye or not, often came on during or soon after some severe illness, whilst in a considerable number the children were syphilitic. Measles, whooping, varicella, and perhaps pyæmia and sporadic recoverable meningitis, appeared from the cases, published and unpublished, collected by the author, to be the commonest antecedents of these eye changes. He asked especially for evidence as to the nature of the communication between the ocular and the constitutional conditions.—Dr. Barlow could recall five of these cases, and in three of them there was reason to suspect the existence of congenital syphilis. But he had not been able to realize their direct connection with that diathesis. He thought the most likely hypothesis was that some of them, at all events, were pyæmic. He had had no opportunity of examining a case post mortem. The nearest approach to the condition described which he had been to examine post mortem was the eye of an adult patient of his, who had ulcerative endocarditis and basic meningitis. This eye presented extensive small retinal hæmorrhages, and opacity of the vitreous, but no suppuration. During life there had been very slight steamingness of the cornea, and some iritis. Whatever the nature of the process, he thought it must begin from behind and come forwards, and that these cases might perhaps only differ in degree from those of panophthalmitis of embolic origin. With the account after general symptoms which Mr. Nettleship had given Dr. Barlow quite agreed. So far as he remembered, in most of the cases there was a history pointing to the probability of a cerebral attack, most likely meningeal. This had lasted for a time, and then come to an end, the definitive character of the brain symptoms being a special feature. In two cases he remembered the children had remained semi-idiotic, and with a certain limpness about the muscles of the neck, so that they were unable to sit up. But the active signs of brain trouble had come to an end as well as the eye lesions.—Dr. Brailey said that he had examined an eye which had been excised for suppuration in ulcerative endocarditis. There was much pus between the choroid and retina, and in that it differed from "pseudo-glioma." In many cases the retina is detached, with suppuration of the vitreous. Mr. Hulke first drew his attention to spontaneous suppuration of the vitreous in these cases. As to diminished tension in "pseudo-glioma" he had seen cases of intraocular hæmorrhage in which tension was increased.—Mr. Waren Tay mentioned a case of cerebro-spinal meningitis with double panophthalmitis, and stated that Mr. Hutchinson had said that in epidemics of cerebro-spinal meningitis it was not uncommon to get this panophthalmitis.—Dr. S. Mackenzie, who had seen a fair number of cases of sporadic cerebro-spinal meningitis, had not found this condition; but double optic neuritis.—Mr. B. Carter referred to an exhaustive report on Epidemic Cerebro-spinal Meningitis by Hirsch, which he had translated for the Epidemiological Society's Transactions.—Dr. Fitzgerald remembered an epidemic of this disease (cerebro-spinal meningitis) in Dublin, and at least one case in which the eyes were destroyed. Since then he had seen cases of panophthalmitis in other affections—e.g., puerperal fever, and in a case of pyæmia following amputation. He believed that Dr. Stokes had pointed out the occasional occurrence of sudden destruction of the eye in heart disease.—Mr. Jas. Adams pointed out that the class of cases described by Mr. Nettleship—viz., "pseudo-glioma"—differed from the embolic and pyæmic cases of destruction to the globe. In "pseudo-

glioma" the cornea remains transparent, and the pathognomonic condition of the iris is plainly to be seen. He had at present under observation one of these cases, in which the vitreous is undergoing remarkable changes. As there is no object in excising the globe in such cases, it would be interesting to learn what changes may take place in the affection when left to run its course.

MEDICAL SOCIETY OF LONDON.

Pathology and Treatment of Whooping-cough.

THE first meeting of the services of this Society took place on October 16th, the chair being taken by the President, Mr. Francis Mason, who in a few introductory remarks, made especial reference to the extensive alterations that were being carried on in the Society's premises. The Fellows would remember that when he had the honor of taking the chair as President for the first time, in March last, he hinted that the Council were contemplating taking additional premises in order to provide increased accommodation for the library, as well as to add to the comfort and convenience of the Fellows. He was now happy to say that that project had been realized, and he believed that, after the completion of the work, the Society's rooms would be second to none in the metropolis. He passed a well-merited tribute to the two honorary secretaries, Mr. E. Owen and Dr. I. Owen, for the zeal displayed in the negotiations, and concluded by reminding the Fellows of the claims the Society had on their support.

Mr. Dolan read an abstract of his essay on Whooping-cough, to which had been awarded the Fothergillian medal of the Society. Dealing with some points of its pathogeny, he expressed his dissent from the view of Guéneau de Mussy, that the malady was a bronchial adenopathy, its chief symptom being induced by pressure on the vagus by the enlarged glands, and showed that this glandular enlargement was not always present in pertussis, and further that the glands may be swollen without producing the characteristic cough. The disease, indeed, bore much resemblance to those diseases the causes of which are now believed to be minute organisms or fungi. Its highly contagious nature, period of incubation, effervescence and defervescence, its regular course, and the immunity from subsequent attacks, were grounds of analogy determining the place of pertussis in the group of diseases caused by protophytic fungi. The attempt by Linnæus to prove that all diseases were produced by animalcula, or had an insect origin, foreshadowed the conclusions now arrived at by the discoveries of Pasteur. In 1867 Poulet found bacteria in the sputa of pertussoid patients, and Letzerich had induced whooping-cough in rabbits by inoculating the trachea with sputa from the human subject. The author had repeated these experiments, and found that whilst inoculation with the blood of whooping-cough patients was without effect, that of sputa and other secretions caused death. He had found also on microscopic examination of sputa ordinary bacteroid forms, and a microbe resembling the spirochæte plicatilis of Cohn. The application of special methods of staining, as employed in the detection of the bacillus tuberculosis, would no doubt reveal the special microbe of pertussis. Admitting the fungoid nature of pertussis, its contagious property was easily explained by germs being thrown off into the air and received into the body, setting up constitutional disturbance, and subsequently attacking the pulmonary epithelium, giving rise to all the phenomena of pertussis. No pathognomonic

lesions could be detected on post-mortem examination, for the simple reason that whooping-cough was rarely fatal; death resulted from complications which were very numerous. As to glycosuria in whooping-cough, he had found it present in fourteen out of fifty cases. Turning to the question of treatment, he pointed out the necessity for measures of isolation in preventing the spread of the disease, for the enforcement of which measures the co-operation of all classes of the community was needed; and although the course of the disease could not be controlled by treatment, the patient could be placed in the most favorable circumstances towards recovery; certain painful and prominent sources of trouble could be relieved and complications guarded against so as to assist nature in her efforts to throw off the disease. There was no panacea or specific remedy, but if the dependence of whooping-cough upon a specific virus be the true explanation of its pathogeny, the lines on which its rational treatment and prophylaxis were to be pursued became clearer and more hopeful.

Cranial Osteophytes in Congenital Syphilis.—Gastrostomy. Inflammation, Suppuration, and Ulceration of Tongue.

At the meeting of this Society on October 23rd, Mr. F. Mason, President, in the chair, Dr. Radcliffe Crocker showed the Skull-cap of a child aged a year and ten months, with well-marked Osteophytes from Congenital Syphilis. The living case was shown last year with extreme anæmia, enlarged spleen, and cranial thickenings, but with no other signs of syphilis. The family history of miscarriages and early deaths was corroborative. The child died from bronchitis. The thickenings were well marked over the frontal and parietal eminences, and on each side of the sigittal suture posteriorly. The borders of the anterior fontanelle were quite thin. The rough drab-colored surface of the new bone was in marked contrast to the smooth, white, healthy bone.—The President thought there was very little evidence of congenital syphilis in the case; and Dr. Crocker said that he relied on the anæmia and enlargement of spleen for his diagnosis, which was confirmed by the existence of the cranial osteophytes.

The President related the particulars of a case in which he had performed the first stage of Gastrostomy. The patient was a man aged sixty, who had carcinoma of the left tonsil, which was growing so rapidly as to interfere with deglutition and respiration to a dangerous degree. The general details of the case have already appeared in *THE LANCET*; the specimen showed the kind of union that had taken place between the parietal layer of the peritoneum and the visceral layer of the stomach, an amount of union not sufficiently strong to justify opening the cavity of the stomach. Had life been prolonged a few days the union would probably have been thoroughly solid. Death took place on the third day after the operation, partly it was thought from exhaustion, but directly from a sharp attack of dyspnoea, for which tracheotomy was performed with temporary relief only.—Mr. Bryant said it was important to determine when the second part of the operation—viz., the perforation of the stomach—should be performed. The parietal peritoneum should be included in the stitches, of which six or eight should be put in close together. Four should be stout, the rest fine ones. His own experience was too small to accurately fix the date for opening the viscus. In one successful case of his, vomiting displaced the adhesions and one of the stitches before the incision was made into the stomach; he therefore delayed the second part of

the operation. In some cases the stomach may be opened on the third day, but if the adhesions are not firm it should be left till the fifth or eighth. In a case of ovariectomy performed by him fifteen or twenty years ago, treated with the clamp, death having occurred on the third day from bronchitis, the abdominal cavity was found to be already closed by adhesions from the external wound.—Mr. Gould had had lately two cases of gastrostomy. In the first the stomach was opened on the third day with difficulty, for the mucous membrane was corrugated and separated from the muscular and serous coats. The tenotome had to be introduced quite up to the hilt before perforating it. Death occurred from peritonitis forty-eight hours after; the adhesions were extremely slight. The patient was in a state of extreme starvation. He expected to find the stomach thinned; and he had therefore been led to make the stitches too shallow. In the second case the dyspnoea was first relieved by tracheotomy. The stomach was opened on the eighth day after the first part of the operation, and food was introduced several times a day. Peritonitis set in two days after, and death took place on the fifth day. The adhesions were firm and the cause of the peritonitis was not apparent. Perhaps the injections of food were too large and too frequent.—Mr. E. Owen preferred Mr. Mason's course of waiting and performing gastrostomy when necessary to that of excising the tonsils.—Dr. Heywood Smith asked how the antiseptics were managed, and spoke of the value of the eucalyptol spray in abdominal operations.—Mr. Bryant had introduced his plan of the two stitches to obviate the difficulty met with in Mr. Gould's case. Much care should be exercised in feeding, and for the first few days only warm milk should be given in small quantities.—The President, in reply, said that he had no experience of the eucalyptol spray; his patient suffered from carbolic poisoning, though the exposed surface was so small. The spray was used throughout the operation. As regards the number of stitches, he thought four were enough, and in this case they were closely set. In the future he should use two needles—a surgical needle to go through the abdominal wall, and an ordinary sewing needle to perforate the stomach.

Mr. Bryant read a paper on some Cases of Inflammation, Suppuration, and Ulceration of the Tongue. He detailed examples of abscess due to injury as well as to idiopathic causes, and showed how this affection has a tendency to get well, and more particularly after an early puncture. He recorded two examples of hydatid of the tongue. The subject of chronic superficial glossitis then received attention, and it was illustrated by cases as well as by a preparation. Superficial ulcerations were then described, and some good examples quoted of the simple dyspeptic ulcer. Ulcers due to local irritation were then described, and cases quoted, in one of which the ulcer had existed for two years, and had been mistaken for a cancer. Deep-seated ulcerations were fully considered, and the differences between the syphilitic, epitheliomatous, and tubercular forms dwelt upon. The tendency for the chronic syphilitic disease of a tongue to pass into cancer was emphasized, and the danger of not recognizing the tendency to the full pointed out. The connection between epithelial cancer of the tongue and ichthyosis was demonstrated, and the local character of the cancer noticed. The necessity for the early removal of a cancerous tongue was strongly enunciated, and some good cases quoted in which a long immunity from the disease, if not a cure, had been obtained. The different modes of operation were then discussed, and statistics given of operations, in which the mortality as a whole from the operation was

shown to be about 10 per cent. Amongst the advantages of the operation was advanced the fact that when a cure does not take place great comfort is given, and that a return of the disease is more likely to occur in the glands of the neck than in the tongue itself. Time not permitting of some remarks being made on tubercular disease of the tongue, it was deferred to another occasion. The paper was illustrated by drawings and preparations.—The President said that in his experience patients seldom survived more than two years after removal of the tongue. Cases of abscess and hydatid of the tongue are rare, and so are cases of cancer in persons under forty. He had operated in a case of cancer of the tongue in a lady thirty-three years of age.—Dr. Rogers asked why Mr. Bryant had given up the use of the galvanic éraseur.—Mr. Hutchinson had had similarly favorable experience in operations for the removal of the tongue in cancer. In very few cases was a second operation on the tongue required. Of course the disease returned very frequently in the lymphatic glands. He agreed with Mr. Bryant that the galvanic éraseur was a suitable and convenient instrument, but preferred the wire éraseur, because (1) of less liability to secondary hæmorrhage, and (2) the wound takes on a more healthy action after the cold éraseur.—Mr. H. Morris spoke of the importance of Mr. Bryant's statements as to the frequency of lung complications in cases not operated on as well as in cases operated on. Two of his own cases related in his paper last session had now lived over two years after the operation. He did not recommend ligaturing the lingual artery in excising, as hæmorrhage was so easily controlled; but in a case of cancerous hæmorrhage from the mouth he had ligatured both facial and lingual arteries (the former to avoid risk of secondary hæmorrhage) with good result, hæmorrhage ceasing, and the patient living for two years after. At the post-mortem examination the usual foul, sloughy condition of mouth was wanting. He asked if Mr. Bryant considered that abscesses of the tongue always healed readily. In one case he was surprised at the rapid healing of an abscess.—Mr. Walsham had also observed rapid healing of lingual abscess. He alluded to the advantage of the cord compressor in removal of the tongue in preventing secondary hæmorrhage and obviating shock.—Mr. Bryant, in reply, was himself surprised at the favorable results of his statistics of removal of the tongue. He strongly believed in cancer being local at the outset. He was not quite satisfied of the superiority of the ordinary éraseur over the galvanic, and did not recall many cases of secondary hæmorrhage after the use of the latter. In one case this was due to the haste needed in operating. In using the cord it had once snapped during the operation, and he preferred a wire to a chain. Mr. Morris's allusion to ligature of the lingual artery was valuable, and he agreed with Mr. Hutchinson as to the infrequency of local recurrence. In one case he removed what was thought to be a recurrent mass a year after excision of the tongue. The patient had lived three years and a half since without further recurrence.

EPIDEMIOLOGICAL SOCIETY.

THE thirty-second session of the Epidemiological Society was opened on Oct. 18th, by a conversazione given by Dr. George Buchanan, F.R.S., to members and friends of the Society, at University College, Gower-street. Among the distinguished company present were the Directors of the Army and Naval Medical Services, and other eminent members of the profession. Several

microscopical specimens, illustrating subjects with the study of which the Society is specially concerned, were shown during the meeting. Among them, preparations of the ova and living ciliated embryos of *Bilharzia hæmatobia*, exhibited by Dr. Cobbold attracted special attention. The embryos were seen making vigorous movements within the firm outer shell of the ovum, which finally ruptured and allowed them to escape. The specimens were obtained from the urine of a patient who had contracted endemic hæmatobia while in Egypt. Dr. Klein also demonstrated specimens of bacillus tuberculosis in the sputum and lung from tuberculous patients, from the lung of a cow suffering from bovine tuberculosis (*Perlaucht*), of the bacilli of anthrax and septicæmia, of the bacilli met with in the Welbeck and Nottingham cases of ham-poisoning, and the micrococci present in the lymphatics in ovine variola, and in the blood and liver of patients suffering from infantile diarrhoea. A section through the tongue from a case of *Actinomyces bovis* also showed very beautifully the stellate masses of fungus, surrounded by a deeply-stained layer of inflammatory exudation, containing numerous leucocytes. Specimens of the embryo *filaria sanguinis hominis* from the blood of a patient suffering from chyluria, and from the Chinese mosquito, were exhibited by Dr. Stephen Mackenzie. Examples of *trichina spiralis* in the muscles of a wild boar, of *draconculus* embryos, of the micrococci of diphtheria, septicæmia, pyæmia, and ulcerative endocarditis, and of the ringworm fungus (*trichophyton tonsurans*) artificially cultivated were also shown by Drs. Bastian, Gibbs, Henderson, Mackenzie and Mr. Malcolm Morris.

The first ordinary meeting of the Society will be held at University College on Nov. 1st, when a paper will be read by Dr. Norman Chevers, C.I.E., "On the Sanitary Defects of the Site of London and its Suburbs."

Editorial.

BERKELEYISM IN MEDICINE.

ALL error has truth for its starting-point, and underlying the wildest flight of fancy there is to be found a solid substratum of fact. The philosophy of Berkeley, antithetical as it is to the prevailing belief in matter as the sole embodiment and source of force, has so much truth in it that only the narrow-minded or unreflecting can wholly reject or disregard it. To the intelligent student of the so-called "medical sciences," and to the practicing physician, Berkeleyism supplies the only key that will unlock a world of mystery, and the only guiding principle in the interpretation of a multitude of obvious but unsafe inferences. Translated into the language and terminology of contemporary schoolmen, the essential principle of this system of philosophy may be said to consist in the recognition that the external—as it stands related to our consciousness, whether through the mental or the physical senses—is the reflection of our own conceptions. What we see, hear, smell, taste, and touch are not—so far as we are concerned—the things themselves, but our sensory notions or impressions of them.

Between us, the internal, and the objects that surround us, the external, the very existence of which Berkeley first doubted, then denied, there intervenes a halo or cloud—the personal environment through which all impressions are transmitted and have to be received; and by which every impression is modified, so that when it reaches the mind, and becomes a conception, it only more or less faithfully represents the external, but is never its true counterpart. This is what happens to that which comes to us through our environment. On the other hand, what leaves us is, so to say, projected upon the mirror-like inner surface of the mental and sensory medium that surrounds us; and just as every pane of window-glass plays two parts in relation to light and its pictures, transmitting and reflecting, so that we see through it, and at the same instant see our own reflection on its surface, so in looking at the external through our environment, we see surrounding objects—albeit distorted by our medium—and at the same moment see our own ideas of fact superimposed upon the external and mingling with it in such fashion that it is difficult, sometimes impossible, to distinguish between the true external and the projected imagery of our own mind-chambers.

There is something more in this than merely “seeing things through our own spectacles,” as the phrase goes, because what we see is, in part at least, not an object but a reflection of self contributed by our “environment.” The existence of such a halo or enveloping cloud of consciousness as we have termed the “personal environment”—in a special sense—cannot be doubted as a subjective experience, although some may be inclined to reject it as a scientific proposition. The personal environment—call it what we may—of the child is blank, and yet it strangely distorts his vision of the external. As time rolls on and his education by surroundings is advanced, the horizon of his perception extends, and his strength of view becomes greater, but the projections of his own thought and fancy multiply, and these stand pictured on the medium through which he looks at the external, so that the life of relation is really a life of experience, and experience is always a thing of self, and determined by the way things affect us rather than what they are in themselves.

It follows that, in a very real and practical sense, for ourselves and others, both subjectively and objectively, we need to analyze every impression or description of an impression, with a view to distinguish between the actual and the imaginary. This is not an easy, and it will often prove a very onerous, duty to discharge, but it is one which must be performed at any pains or cost, if we would avoid being deceived and deceiving others. In the study, in the consulting-room, at the bedside, in the laboratory, or in the post-mortem room, in scientific investigation, and in practice, it is indispensable to be severely scrutinizing and to keep the inevitable, and in a way natural, mingling of

the real and the unreal always in mind, if we would be accurate. It follows also that what we have called the “personal environment” is the source and field of impressions and visions which are ideal although they seem actual. Failure to recognize this fact makes otherwise intelligent and truth-loving minds the victims of self-deception in the matter of many of the occult phenomena—for example, those of spiritism, mesmerism, hypnotism, metallo-therapy, and the host of half-truths distorted and transmuted to errors by the intervening influence of the environment with its mental reflections and sensori-motor reflexes.

It is absurd to suppose, and vexatiously wanton to assume, or try to prove, that all the believers in these “isms,” which have done, and are still doing, much to retard the progress of rational science, intentionally deceive either themselves or others. They are simply persons who, from the habit of their intellectual and mental work—using the latter term in its broadest sense—do not recognize the existence, and therefore make no allowance for the influence, of the enshrouding medium which interposes between every consciousness and the external. Ghosts, spirits, waking dreams, dozing dreams, sleeping dreams, and any and all of the objecto-subjective phenomena of consciousness, whether in health or disease, may be real—as real as anything can be—to those by whom they are witnessed or experienced.

The student or practitioner who does not perceive and—which is more to the point—bear constantly in recollection these facts about mental reflection can never be quite safe as regards his own impressions and the use he makes of descriptions of impressions; nor can he be a perfectly trustworthy reporter of experiences and observations for the information and guidance of those with whom he is associated. It is always timely to raise a warning cry in presence of the peril of errors growing out of truths; but it is especially seasonable to call attention to the subject at the commencement of a new session of study and clinical work, in the course of which we are sure to be treated to the narration of divers marvels. It would be well if we could incorporate a spice of Berkeleyism with the crude materialism of what is now deemed rational medicine.

THE CLINICAL TEACHING OF MIDWIFERY.

THERE can be no doubt of the vast importance of, as well as the necessity for, the effectual practical teaching of Midwifery in our medical schools. The great majority of all those who engage in the private practice of medicine are called upon to attend women during their lying-in. A very large proportion of women who suffer from diseases peculiar to their sex refer their suffering to a previous labour, and justly. It has been proved that the mortality in childbed is very great—about 1 in 120; and in all cases of difficult labour two lives,

that of the child and that of the mother, are at stake. These facts sufficiently testify to the importance of midwifery as a branch of medical education, as well as to the necessity of teaching our students the practical details and management of labour in all its varieties. The methods adopted in the English schools differ materially from those in use on the Continent. In France, Germany, and Austria large lying-in hospitals are common, and it is not an infrequent practice to conduct difficult cases of labour in the theatre before a crowd of students when any obstetric operation is to be performed. In this country, on the other hand, such practice is unknown, and the sentiment of the public would doubtless be altogether opposed to its adoption. At the same time, if the practice were of such value that it supplied the student with a knowledge of operative midwifery which he could not otherwise obtain, and in this way proved conducive to the safety of the public, poor as well as rich, the sentiment would be unreasonable, and should be as far as possible treated accordingly.

Operations in midwifery differ from most other operations in this—that they are performed, not under the guidance of the eye, or of the eye and the touch, but of the touch alone. They are done within the pelvis, and little or nothing is to be seen; and witnessing the forceps applied, the perforator used, internal version or any other purely obstetric operation performed, can give the student little or no idea of the manipulation necessary to their safe performance. He can acquire a knowledge of the subject only by doing such operations himself. This knowledge would of course be best acquired on the living subject, under the supervision of a competent teacher. Cases of operative midwifery are, however, not so frequent as to permit of this, and we have to fall back on the next best alternative—operating on a well-made model. By the latter method the student can acquire a fair knowledge of the use of instruments, as well as a certain amount of skill in obstetric manipulation—a knowledge which will enable him to operate successfully and without inflicting injury in the great majority of cases. A knowledge of how to use instruments is not more important in operative midwifery than a knowledge of when to use them. The latter is far more difficult of acquisition than the former. Examination in the living pelvis alone can supply it; and it is in the education of the student in this part of midwifery that lying-in hospitals may prove of the greatest value. There are in London a considerable number of large maternity charities, in some of which thousands of women are attended every year, others in which the patients are counted by hundreds. Several of the largest are connected with our medical schools, and the cases are attended by students. There are others in which all the work is done by midwives, under the supervision of physicians. This material is enormous; but it

is not possible at present, and as the work is now carried out, to make the best use of it in the interest of the public or of the student. For teaching purposes a great part of it is not available. The women attended by the students from our schools dwell in wretched rooms scattered over wide areas, so that not more than one can benefit by each case, and it is not possible for that one even to derive that legitimate advantage from it which he would derive were the patients gathered within a small area where the teacher could personally superintend the labours. For this object lying-in hospitals are necessary, and nothing else can supply their place. There are four lying-in hospitals in London, and, with one exception, there is not the least attempt to utilize the material in them for teaching purposes. We cannot but think that it would be greatly to the benefit of the public, and especially of the poorer classes, where these made teaching in addition to charitable institutions, and were students of our medical schools permitted to enter them under some strict regulations. There would be no difficulty in drawing out a working plan which would prove mutually beneficial to institutions and students, as well as safe for patients.

THE CONSTRUCTION OF SMALL-POX HOSPITALS.

WHEN commenting on the report of the Royal Commission on Small-pox and Fever Hospitals, we referred incidentally to a proposal by Dr. Burdon-Sanderson, F.R.S., for the construction of small-pox hospitals in such a manner that none of the hospital air could leave the hospital buildings without being first submitted to such a heat as would effectually destroy all organic and infective matter. Since then we find that the subject has received attention elsewhere, and there is evidently an increasing desire so to deal with our future small-pox hospitals as to prevent their becoming possible centres of infection, either by means of aerial diffusion or otherwise.

Dr. Burdon-Sanderson's proposal is to construct a hospital with one ward, for twelve patients, of an annular shape on a floor slightly raised above the surrounding ground, and if necessary to increase the accommodation by the construction of one or two more similar wards on a second and third story. In the outer wall of the annular ward, and just above the floor level, are a series of openings into the external air, and in the inner wall, above the head of each patient's bed, and immediately opposite each of these openings, is a similar opening leading to a chamber which forms the centre of the ring. It is intended that this chamber shall be fitted with an extraction-fan, and in its roof would be fixed a gas furnace. All the windows would consist of fixed sheets of glass, and with the exception of doors carefully guarded by springs, and communicating with a corridor, there would, apart from the apertures in the outer wall

of the ward, be absolutely no openings into the external air. Under these conditions, and by the aid of the fan in the central chamber, it is alleged that the air, having first passed over hot-water pipes, would be drawn into the ward through the openings in the external wall, that it would be conveyed at the rate of about one mile an hour over each patient's bed, and that the beds being guarded on either side by septa projecting into the ward, the air would pass out of the openings near the ceiling level in the inner wall of the ring, from which point it would be drawn by the fan up into the furnace. By means of this operation each patient, having 1,200 cubic feet of ward space, would be provided with 10,000 cubic feet of air per hour, and thus it would seem that a quarter of a million cubic feet of air per patient per diem would have to be treated by heat. Dr. Burdon-Sanderson, as the result of his experiments, anticipates that no difficulty would be experienced in securing this end, and he has shown in his description of the proposed hospital how the various necessary administrative details could be attended to without disadvantage to the patients or the staff.

Another scheme, prepared before the publication of the Report of the Commission, was recently submitted to the Leeds corporation by Messrs. Harding, engineers of that town. According to this plan, inlets for fresh air are placed above windows which consist of fixed sheets of glass, and over each patient's bed is a funnel-shaped hood, communicating with a tube which passes round the walls of an ordinary oblong ward, and is then conveyed beneath the flooring to a furnace in an adjoining apartment. The furnace thus exercises an extracting power, and it is assumed not only that none of the air-inlets will become outlets, but that all the ward air will gradually be drawn up the hoods over the beds, and so on to the surface of the fire, where it would be deprived of its infectious qualities.

The principal difficulty which we anticipate in the actual working of a hospital in which every movement of air and all ventilation must, in order to complete success, be dealt with artificially, and in which all air must be drawn out of, instead of driven into, the building, is that of ensuring that none of the openings into the external air shall, under any circumstances, become outlets instead of inlets. Artificial methods of ventilation seldom answer all the ends they were hoped to have attained; and even where the current of air is with certainty directed into the intended channel it is often done at the expense of creating draughts. Of the two schemes we have noticed, we cannot but think that the desired end is more likely to be gained by the plan submitted to the Royal Commission by Dr. Burdon-Sanderson. The warmer air in the upper part of the ward is the air which it is most essential to remove, and this would perhaps be best secured by making the outlets at a much higher level than the inlets, and by fitting both

the machinery of the fan and the furnace with gas, which would continue to work without the need of that constant supervision which always becomes necessary in the case of an ordinary furnace dependent for its efficient working on human labor. Under any circumstances, if the temperature to which the out-going air were subjected in the furnace could be maintained at such a height as to ensure the destruction of all its organic matter with such instantaneous rapidity as would be essential, owing to the necessary velocity of the air-current, a very large proportion, if not all, of the infected air emanating from the patients would be destroyed before it left the hospital buildings, and such portion of it as might find egress by air inlets not sufficiently under the control of the general ventilating machinery, would probably be so small that even in connection with a building containing some thirty-six beds, it would never lead to that mischievous condition of atmosphere in the neighborhood of the hospital which appears to need for its production the aerial emanations of an aggregation of at least some such number as thirty small-pox patients. In short, it is quite possible the suggestions which we have commented on in this article may ultimately be found to indicate a remedy for the dangers which have been shown to attend upon the isolation of any large number of small-pox patients in the neighborhood of centres of population.

BACTERIAL PATHOLOGY.

THE actual value of new discoveries in science can never be at once appraised. It is long before the true relations of fresh facts can be ascertained. They are magnified by the halo and novelty which surrounds them, and which itself depends on the mists of ignorance that prevent us from estimating the proportions, and discerning the position, of a new light in the sky of science. Sometimes a discovery at first is undervalued. Modest and unobtrusive in appearance, its significance is only realized when long-continued observation has shown its true position, or revealed the order to which it is the key. Much more frequently the influence of a new discovery is over estimated. Expectation is aroused by the trumpet-blasts which herald its approach, and the discovery is received with universal acclamation, as explaining all things, or about to explain them—as affecting all things, or about to affect them. This is rarely the fault of the discoverers themselves. New facts are never brought to light but after long and patient search, and he who is most familiar with the region in which the discovery is made is least likely to exaggerate the value of the fresh-found truth. Of no advance in medical science is this more probably true than of the wave of discovery on the crest of which pathologists now find themselves. Far be it from us to undervalue the remarkable facts of the relation of living organisms to disease, which have been ascertained by the

not less remarkable investigations of the recent years. Their profound importance is beyond all question, and they will certainly constitute a chief landmark of the progress of medical science in the present century. But in the profession, and even more outside it, there has been, and still is, a widespread expectation of practical results of the highest importance from these discoveries—an expectation of an immediate and vast increase in our power of dealing with disease, of preventing its occurrence, and of curing it when it has developed. A caution is needed against such exaggerated expectation. That "knowledge is power" is not, alas! an aphorism of universal application. Doubtless, no great advance in our knowledge of disease can ever occur without entailing some increase in our power of coping with it, but every consequence does not closely follow its cause, and though knowledge comes, wisdom, its practical application, lingers on the way. It may be doubted whether there is at present any satisfactory evidence that these discoveries have yielded the slightest increased power of dealing with the diseases of mankind. Most, if not all, the means of treatment and of prevention, which they suggest, have been in use before, and if they have suggested some new methods, the value of these has not yet been proved by practical results. The discoveries enable us to understand the *modus operandi* of certain influences, morbid and therapeutic, more clearly than before, but there are others on which these new facts do not at present throw the faintest light.

We may take as an instance the remarkable discoveries regarding the relation of bacteria to tuberculosis. These have been at once received as evidence of the contagiousness of phthisis. All that they really do is to enable us to understand how phthisis may be contagious. They afford no proof that it is, and at present there is no more evidence of its contagious character than there was before. Rare instances of its apparent communication from one person to another have long been recorded, and before the discovery of the organisms there was some evidence—not very strong, however—to show that the disease may be produced by the consumption of the flesh of diseased animals, and still slighter evidence that it may be contracted from milk. But this is all. Indeed, so far as the indirect influence of the discovery can be traced, it has rather increased the evidence to show that the disease is not contagious, for it has led to the collection of facts, such as those lately published by Dr. Theodore Williams, which prove that the conditions of aggregation, which conduce most powerfully to the extension of really contagious diseases from the sick to the well, are without influence in the case of phthisis. On the other hand, the discovery of the bacteria has increased the difficulty of explaining the influence of heredity, and still more the influence of subsoil drainage on the occurrence of the disease, so ably worked out by

Dr. Buchanan. It has led to the adoption of antiseptic expedients in the treatment of phthisis, to the suggestion of numerous inhalers and inhalations, but there is at present no evidence of their specific utility to the patients, although there is considerable evidence that they are of practical value as a means of displaying the names of physicians on the counters of chemists.

The discoveries and inferences regarding the relation of organisms to acute specific diseases force the same conclusions upon us, and also upon others, if we may judge from the cautious utterance upon the subject which Prof. Jaccoud lately delivered, in a lecture inaugural to his course of medicine at Paris. The question of the origin, prevention, and treatment of the acute specific diseases of man remains exactly as before the discovery of the relation of special organisms to some of them. Very wisely does Prof. Jaccoud warn his hearers against the "exclusivism" which would regard the bacteria as all and everything in the pathology of disease. He reminds us that the liquids in which bacteria grow have been proved to have toxic properties apart from the formed organisms, and that even the right to accuse bacteria of being the infective agents where they have been found, does not give us the right to accuse them where they have not been found. It is still unproved whether the different bacteria are of specific nature, or whether they acquire specificity under certain conditions of development. "Knowing," he concludes, "the influence of the infected bacteria, we know one of the agents—say, if you will, the most powerful agent—in the diffusion and conservation of infectious diseases; but this conception still leaves us as ignorant of the morbid poison itself, leaves us as powerless in direct prophylaxis, as we were when we spoke of miasma instead of bacteria. Now, as then, we can only learn the real causes of these diseases by ascertaining the conditions in which the infective agents, judged by their effects, arise; by ascertaining the circumstances which limit or facilitate their diffusion; and by ascertaining what conditions, cosmical and personal, are opportune for their development."

Reviews and Notices of Books.

Chapters in the History of the Insane in the British Isles. By D. HACK TUXE, M.D., F.R.C.P. London: Kegan Paul, Trench & Co.

DR. HACK TUXE'S work is an addition to the literature of insanity that was greatly needed; it has been executed at the right time, and the author is in every way qualified for the work he has undertaken. His book manifests a wide and liberal comprehension of this subject; bears evidence of a most intimate and thorough knowledge of all relating thereto; and shows a most laborious, exhaustive, and painstaking power of research, together with an impartiality and freedom from

prejudice most remarkable in one so intimately connected with and so deeply interested in his subject. The wish might perhaps be expressed that Dr. Tuke had not been so simply historic, but had at times appended his own conclusions in regard to the opposing opinions so clearly and fairly stated. In manner the facts are well put and interestingly associated. The book will not only be a medical classic, but will be read with interest by laymen, and may thus greatly aid in dispelling the ignorance that exists in the public mind in regard to asylums and the treatment of the insane.

The early chapters trace the popular idea of insanity, from the belief in demoniacal possession prevalent in early Saxon times, to the later beliefs in witchcraft and peccant humors in the blood. Side by side with this, the treatment is given, often amusing, in the mixture of exorcism, of superstitious spells, and of emetics and purgatives, with flagellation.

The history of Bethlem and St. Luke's displays a great amount of interesting antiquarian research, and affords an opportunity for the comparison of the former and present treatment of the insane by the introduction of plates representing a ward in Bethlem in 1745 and one at the present day, the details of which are more convincing than any words could be. A sketch of the miserable state of lunatic asylums in England, emphasized by the unfavorable comparison made by John Howard between St. Luke's and an asylum in Constantinople, is followed by the history of the foundation of the York Retreat in 1792 by William Tuke, the grandfather of the author. The principles for the moral treatment of the insane, laid down by this noble man, and quoted here, must ever remain as fundamental truths.

The history of the legislation for lunatics is next carefully traced, with the date of establishment and cost of the various principal asylums, acknowledgment being made of the great share taken in this work by the present chairman of the Lunacy Commission, Lord Shaftesbury.

In the next chapter the development of the non-restraint system is shown. The first efforts were made at the Lincoln Asylum by Dr. Charlesworth from 1819 to 1835, and from that date to 1839 by Mr. Gardiner Hill, who was the first to assert the principle of the entire abolition of mechanical restraint. Drawbacks in the shape of broken ribs, etc., at the Lincoln Asylum, as Dr. Tuke points out, might have produced a reaction but for Dr. Conolly's success at Hanwell, leading to the almost universal adoption of the principle in Great Britain. The disadvantage of large asylums in the loss of "individual and responsible supervision" is quoted from the Report of the Commissioners in Lunacy for 1857; regret must be expressed that this principle has been so much lost sight of in later years. The assertion made in the same report that large asylums are more costly than small is refuted by statistics, in an appendix. It should be remembered, however, that an economy may be apparent only.

Chancery Lunatics form the subject of another chapter, in which Dr. Lockhart Robertson's comparison of the 34.6 per cent. of those patients treated in private houses with the 6 per cent. of private patients so treated under the Lunacy Commissioners is reproduced.

In the chapter on Idiots and Imbeciles attention is drawn to the fact that accommodation for the teaching and training of this class in England is only provided for 1,147, or 3 per cent. of the estimated total in the population. Dr. Tuke advises the establishment of additional training institutions, and quotes the conclusions of the Charity Organization Society on this subject.

The history of the insane in Scotland is given in a very interesting form. It is noteworthy that so early as 1838, in some Scotch asylums amusements and employment were very fully carried out, while in 1855 the condition of the insane in many others was of a deplorable character. The points of treatment coming into vogue in Scotch asylums are also dwelt upon, such as the abolition of airing courts, the open door system, and liberty on parole.

In Ireland, so late as 1815, it was reported to a special commission "that when a strong peasant becomes insane the only way they have to manage is by making a hole in the floor of the cabin, not high enough for the person to stand up in, with a crib over it to prevent his getting up." Dr. Tuke traces, with his usual care, the legislation by which this condition of things has been amended.

The book concludes with the interesting address on the progress of psychological medicine during the last forty years, delivered by Dr. Tuke to the Psychological Association in 1881.

No one can arise from the perusal of this work without feeling an increased interest in the advancement of the humane treatment of the insane; and the hope may be expressed that this book may exercise an important influence in preventing the principle of "personal treatment," advocated by his illustrious ancestor, from being overlooked or ignored, in the tendency to excessive size in asylums, which an erroneous idea of economy is now developing.

Die Öffentliche Reconvalenscentenpflege. Von Dr. PAUL GUETERBOCK. Leipzig: F. C. Vogel. 1882.

THIS work relates to the treatment and management of convalescents in homes and in hospitals. All points connected with this subject are discussed fully in every detail, so as to make the volume extremely valuable for purposes of reference. The first portion of the work especially aims at establishing beyond all question the necessity for the existence of convalescent institutions, and the importance of treating convalescents from a public health point of view. After considering most of the details connected with their situation, construction, and management, the author gives a plan and account of the asylum at Vincennes, and another of Burdett's "Convalescent Cottage Hospital." He takes these two as typical examples of what convalescent hospitals should be, although they are constructed on different principles. The vexed question of day rooms is fully gone into, and although Dr. Gueterbock approves of them as a whole, still he recognizes Miss Nightingale's objection as to the difficulty of preserving discipline in them. He insists that patients recovering from chronic maladies should be just as much entitled to admission as those after acute diseases, and also that the treatment of convalescents should not be considered purely as a matter of charity. The second part of the volume is devoted to the special consideration of the working of the system in those European countries where it may be regarded as having taken firm root—namely, in Germany, England, and France, brief mention also being made of Italy, the Netherlands, and United States of America. It is flattering to read page after page of testimony to the efficiency and excellence of the English establishments. The boarding-out system is also highly extolled; although the author wisely remarks on the necessity of a very careful choice of boarders; not so much on account of their special ailments as of their moral character and social condition; in his opinion it is especially of advantage in chronic cases. Dr. Gueterbock, however, has apparently not become acquainted with the excellent results of the system obtained in connection

with the Cork Union, which were published not long ago in *THE LANCET*. In conclusion, the volume dwells upon the position of Germany as regards public convalescence; and the author deplores the backwardness of his own country and the lack of interest taken in the question by its people. We can cordially recommend Dr. Gueterbock's book; it is sound, practical, and thoroughly trustworthy, and fully maintains the credit the German school has obtained for producing works of solid information based on industrious research and high scholarship.

The Journal of Anatomy and Physiology. Conducted by Professors G. M. HUMPHRY, WM. TURNER, and J. G. McKENDRICK. Vol. XVII, Part I. October, 1882. London: Macmillan & Co.

THIS number contains eleven articles, namely:—
1. The Lymphatics of the Walls of the Larger Bloodvessels and Lymphatics, by George and Elizabeth Hoggan. 2. Micrococcus Poisoning, by Alex. Ogston. 3. Omphalo-Mesenteric Remains in Mammals, by Dr. W. Allen. 4. The Action of Saline Cathartics, by Matthew Hay. 5. A hitherto undescribed Fracture of the Astragalus, by Francis Shepherd. 6. A Secondary Astragalus in the Human Foot, by William Turner. 7. Note on the Rectus Abdominis et Sternalis Muscle, by G. E. Dobson. 8. Ectopia Vesicæ, and other Imperfections of Development in a New-born Infant, by Francis Ogston. 9. Nickel and Cobalt, their Physiological Action on the Animal Organism, by Dr. Anderson Stuart. 10. A Kerato-thyro-hyoid Muscle as a Variation in Human Anatomy, by S. G. Shattock. 11. Cæsalpino and Harvey, by Professor Humphry.

Schematic Anatomy; or, Diagrams, Tables and Notes, treating of the Association and Systematic Arrangement of Structural Details of Human Anatomy. By W. P. MEARS, M.B., co-Lecturer on Anatomy, Supervisor of Dissections, and Medical Tutor at the Durham College of Medicine, Newcastle-upon-Tyne. London: Baillière, Tindall & Cox. 1882.

THE aim of this work is decidedly novel. Students and lecturers have always made use of diagrams and notes of associated facts in learning or teaching the numerous details of human anatomy, but we have never before seen such an ambitious attempt at "aids to memory" as is here presented to us. The bones, ligaments, muscles, vessels, and nerves are tabulated and delineated—we cannot say described—and we are promised the viscera in a second volume. The student is recommended to display the facts on the dead subject in the first place, and then to fix them in his memory by means of a corresponding schema or diagram. If there were any real relationship between the dissected part and the mathematically-drawn figures in this work, it would be a valuable addition to the text-books used by the student, but the more elaborate the schemata and diagrams become, and the more closely the associations are urged, the more apparent are their divergences from the true details of human anatomy. In the sketch of the femur, facing page 36, the relative attachments of the muscles are inaccurately shown, for the insertion of the adductor longus is made to correspond in extent with the origin of the femoral head of the biceps, and more space is allotted to the plantaris than to either head of the gastrocnemius. The diagrams of some of the

plexuses are most extraordinary, and representations by exactly similar outlines of the inferior dental, gustatory, glosso-pharyngeal, and hypoglossal nerves and their branches (p. 176), must confuse the student rather than diminish his labors. The book has evidently caused Mr. Mears much trouble and thought, but an instance on the constant use of the scalpel and forceps is the only true method of teaching anatomy, and a few diagrams and tables constructed by the student himself from his own dissections will remain much longer in his memory than the elaborate and somewhat complicated system drawn up by the author.

The Tissues and their Structure. A description of the Elementary Tissues of the Human Body. By A. S. KENNY, M.R.C.S.E., Senior Demonstrator of Anatomy in King's College, London. London: David Bogue. 1882.

THIS small work of 120 pages contains a very clear and accurate description of the elementary tissues and their functions, and is especially adapted for beginners in histology. It will enable them to form some conception of the general structure and functions of the tissues which they are practically investigating, and should be used with the text-book, which directs them how to proceed with their manipulations. The book is well printed, and the illustrations, many of which are quite new, are excellently drawn.

The Compend of Anatomy. By JOHN B. ROBERTS, A.M., M.D., Lecturer on Anatomy and on Operative Surgery in the Philadelphia School of Anatomy, etc. Second Edition, revised. London: Henry Kimpton. 1882.

THE fact that a book has rapidly run through a first edition is a recommendation in its favor, but we entertain a great distrust of small works that assume to give concise statements of what is deemed essential to the student in human anatomy or any other science. This distrust is not removed by the volume before us, for all the *essential* details are contained in less than 200 pages. The necessary conciseness has been obtained at the expense of adequate description, for the only details of muscles and nerves which the author gives are those which can be seen at a glance in a series of tables. It is announced in the preface that the statements and general arrangement of Gray have been followed, and this is evidently true, for the book appears to us to be merely an abridgment of that work, whilst many of the advantages and excellences of the latter are lost. The only novelty is a partial substitution of English names for Latin ones, and this is not always an unmixed gain—e.g., is "compend" a better word than "compendium"?

Publications of the Association for the Advancement of Medicine by Research. London: J. W. Kolokmann. 1882.

THE Association for the Advancement of Medicine by Research has issued its first batch of publications, consisting of four pamphlets. They are none of them new, but are reprints of addresses on the aims, methods, and purposes of scientific experiments on animals. We are glad that the Association has utilized the excellent address of Mr. Simon at the opening of the State Medicine Section of the International Medical Congress. This bears the title of "Experiments on Life," as funda-

mental to the science of preventive medicine, and set forth in a most masterly manner the value and extreme economy of direct experiment upon living animals. Two other of the pamphlets regard the practical results to surgeons of vivisectional experiments; these are Dr. Humphry's short address at Hyde, entitled "Vivisection; what good has it done?" and Dr. McDonnell's address delivered before the Surgical Society of Ireland, entitled "What has Experimental Physiology done for the Advancement of the Practice of Surgery?" With the former of these our readers are familiar, as it has already been widely circulated among the profession, with whom it is judged to have but one failing—brevity. Dr. McDonnell's Address is an extremely useful one, and deservedly ranks with those already mentioned. No attempt is made to detail all the benefits surgery has derived from experiments on animals; reference is chiefly confined to their value in the study of anaesthetics, the introduction of the administration of potent remedies by hypodermic injection, the bloodless surgery now so generally practiced, the arrest of hæmorrhage, and the treatment of wounds. The fear that performing or witnessing such experiments blunting the moral perceptions is shown to be entirely groundless. The fourth of this series of pamphlets is Mr. Wm. Bowman's Address in Surgery, read at Chester, at the meeting of the British Medical Association in 1877. The main topics of this address are the essential unity of the art, its dependence upon science, and the advantages of union and organization for the promotion of common objects. Incidentally Mr. Bowman vindicates the right and duty of experiments on living animals; and this it is, we presume, which leads to the republication of this address at the present time, and in its present form. We congratulate the Association on so quickly setting to work, and on the choice it has made for its first publications, which we hope will be very widely read and studied. The best support the profession can give to the Association is to become apt pupils, to avail themselves of the opportunities afforded of obtaining thorough acquaintance with the part scientific experiments have played in the vast strides our art has made during the last century; and a wise distribution of their pamphlets among the more intelligent of the general population will also greatly aid the cause we have at heart.

Die Parasitären Krankheiten des Menschen. I. Entwicklungsgeschichte und Parasitismus der Menschen Cestoden. Von SIGMUND THEODOR STEIN. (*Parasitic Diseases of Man. I. Developmental History and Parasitism of Human Cestodes.* By SIGMUND THEODOR STEIN.) Lehr: Schauenburg. London: Trübner. 1882.

THIS handsome monograph upon the very interesting class of tapeworms is, as the title-page and introduction inform us; but the first of a series of similar works dealing with the parasites of man that Herr Stein has in view. He intends to issue another part dealing in like manner with the nematode, trematode, and arachnid parasites; a third with the dermatozoa, epizoa, and epiphytes; a fourth with the protozoa, infusoria, and fungi. The present treatise commences with a brief historical introduction, in which the labors of von Siebold, Leuckart, and Küchenmeister are especially dealt with; but we fail to find any reference to English writers in this place. In justice to the author, however, it should be added that in the body of the work he shows himself fully acquainted with Dr. Cobbold's labors. The first chapter deals

with the larval condition of tapeworms, and is copiously illustrated with figures of mealy flesh and the cysticerci. Indeed, the whole volume is most fully adorned with engravings, in addition to fourteen large photo-lithographic plates at the end. The second chapter treats of the developmental history of the human tapeworm: first the characters common to *Tænia solium* and *T. saginata* (*T. mediocanellata*) are described, and then the differential points. Then comes a description of each of these worms in the adult form, followed by full and minute details as to the formation of the generative organs and the development of the embryo. The genus *Bothriocephalus* forms the subject of the third chapter; the same minuteness of description characterizing the previous studies being also shown here. Of course, most of this chapter deals with the common form, *Bothriocephalus latus*; but a section is devoted to the rarer species, *B. cordatus* and *cristatus*. In the fourth chapter we have descriptions of such rarer *tæniæ* as *T. nana*, *T. flavopuncta*, *T. cucumerina-elliptica*. The fifth chapter is entitled, "The influence of tapeworms and their progeny on the human body, including therapeutical measures." The sixth chapter treats of the echinococci, and concludes the work. The following figures compiled from Davaine, Cobbold, Finsen and Neisser are interesting as showing the comparative frequency of hydatid disease in various organs:—Out of a total of 1,862 cases, the liver was the seat of the parasite in 953, intestinal tract in 163, lungs and pleura in 153, kidneys, bladder, and sexual organs in 186, brain and spinal cord in 127, bones in 61, heart and bloodvessels in 61, and other organs in 158. The work bears evidence of considerable original research and an extended study of the literature of the subject.

Spirillum Fever (Synonyms, Famine or Relapsing Fever), as seen in Western India. By H. VANDYKE CARTER, M.D. Lond. London: J. & A. Churchill. 1882.

THE terrible famine that ravaged the western provinces of India some five years ago was succeeded by an epidemic of fever which in its leading features was unlike any other type of fever hitherto recognized in that country. As the sick flowed into the great centres of population, the fever spread there also, and Bombay became the focus of an epidemic; its hospitals were crowded with patients, and a medical commission was soon actively engaged in studying the disease. Chief amongst these was the author of this work, who has here presented us with the results of his investigations and matured experience. Taking up the work with his characteristic thoroughness and energy, it may truly be said that he has probed the disease to the bottom, and his monograph will occupy a foremost place in literature. It is a monument of patient, prolonged, and exhaustive labor; and adds to the reputation of its author as a careful and conscientious investigator.

We have indicated that until the occurrence of this epidemic, relapsing fever was hardly known in India. This no doubt was because, as Murchison, indeed, points out (and Hirsch writes in the same sense), it had been confounded with "bilious intermittent" and other tropical fevers of malarial origin; and this or a like confusion relapsing fever probably shares with other specific fevers, modified by the climatic conditions under which they arise. There can be no question at all as to the identity between the fever described by Dr. Vandyke Carter and the relapsing or famine fever formerly so well-known nearer home. Ireland used

to afford the most numerous examples of epidemics of this contagious famine fever, and Scotland and England have suffered also, but not of late years. We question whether a single case has been seen in London during the past ten years. No doubt there is great cause for congratulation in this fact, although it has prevented our home physicians from following up the remarkable discoveries which more than any other have so stimulated research into the relation between micro-organisms and specific diseases—we mean the discovery by Obermeier, of Berlin (who fell a victim to his zeal), in 1873 of the spirillum in the blood of patients suffering from relapsing fever, of its occurrence during the pyretic paroxysms, and its disappearance in the apyretic interval. The peculiar form of the bacterium and its constantly observed presence in such cases soon led to the discovery being confirmed wherever opportunity offered. Such an opportunity came to Dr. Vandyke Carter and his colleagues in this Bombay epidemic; the result being that Obermeier's researches were not only confirmed, but the essential part played by the organism became so evident that, as the title of this work shows, the term "relapsing" has been thrust aside, and for it has been substituted the name by which the bacterium is denoted. It is at all times a hazardous thing to import new terms to designate well-known affections, and some may doubt the wisdom of Dr. Carter's step. For it will be long before the phrase "relapsing fever" will be universally discarded, even although, as Dr. Carter insists (and this is the strongest justification for the change he adopts), there are many cases in which the "relapsing" feature, hitherto adopted as the criterion of the disease, has been lacking, whilst the other, and on scientific grounds the sounder criterion—viz., the presence of spirillar infection—has been present. The occurrence of the spirillum as the leading and most constant feature of the disease cannot, after these researches, be gainsaid; and when to this is added the fact of the high degree of contagiousness and the results of inoculation, which Dr. Carter and Professor Koch have successfully performed, there is left no room for doubt as to the very important part played by the spirillum in the disease.

Dr. Carter's work deals first with the history of the epidemic upon which it is based, and shows that the cases occurring in Bombay were imported or developed by contagion from these. He contrasts the prevalence of famine and the fever, and raises the interesting question whether relapsing fever may not now become endemic in Bombay as in other regions. The occurrence of cases since the epidemic and within the last twelve months is in favor of this. The clinical history of the disease is dealt with in a most exhaustive manner, first by a general summary, and then in a very elaborate analysis of each symptom, of the pyrexia and its variations, and of complications. Many illustrative cases are given, and the amount of information sifted and analyzed is very great. Chapters on its mortality, on the anatomical lesions, on diagnosis, prognosis, and treatment, follow; but it is not possible within our present limits to analyze these here, and we prefer to pass to the section entitled the Pathology of Spirillum Fever, as it contains those facts which, where all is interesting, are perhaps of most interest.

The examination of the blood is fully detailed, and its characters during the non-febrile and febrile stages are described. In the incubation period, as observed chiefly in inoculation experiments on monkeys, the main difference from normal blood consisted in the presence of granular protoplasmic masses, and by the third day a few spirilla, and during the apyretic intervals in man

protoplasmic granules preceded the first appearance of the parasite as the pyrexial stage was reached. In the febrile stages, during the first attack, the spirilla increased in number until the height of the pyrexia, when they rapidly disappeared, being replaced by granular masses and an increased number of leucocytes. In the first relapse the spirillum reappears and remains longer than in the primary attack; in the second relapse it is less abundant, and in cases of third and fourth relapses the spirillum is often not seen, but only some immature filaments. By means of charts the author represents graphically the fact of the increase in number of the spirilla concurrently with the rise of the pyrexia in two typical cases of the first relapse, and gives the following data as pointing to a "real connection of spirillar blood contamination with the pyrexial attacks of relapsing fever:—(1) Infection is always followed by fever. (2) With the advent and progress of pyrexia the blood-parasites increase. (3) They disappear with the cessation of fever. (4) By contact with the sick and by inoculation of blood containing the spiral organisms or their germs, the disease may be conveyed to new or old subjects." And he adds as "modifying the connection above implied—(1) The presence of the blood-parasite during several hours, or for one or two days, prior to fever. (2) The sudden onset of pyrexia is not preceded by or attended with a proportionate visible augmentation of the spirillum. (3) The absence of any fixed relation between variation in form and intensity of fever, and varying numbers of the organism. (4) The persistence of the parasite during pseudo-crises and defervescence by lysis." (p. 361). In the next chapter, dealing with etiology, we find much valuable information upon the propagation of the fever by contagion and by direct inoculation (as in the making of post-mortem examinations of infected subjects), with the important conclusions that the disease spreads solely through means of actual contact with the sick; and that no immunity is conferred by a first attack. The author indicates the cutaneous transpiration and the breath of the sick as the probable channels of contagion. The concluding chapter upon the nature of the disease is a review of its main features in the light of the doctrine of spirillar infection. "Regular relapsing fever was never seen without spirillar infection, and though the infection may fall short of producing such clearly recurrent fever, yet it always tends to induce it. The question whether or not the spirillum alone and *per se* produces the fever cannot be answered until the organism be completely isolated and its pathogenic power tested then as well as after cultivation in other media than the blood. At present no pathologist has succeeded in doing this; but in some comparative instances (e.g., the organisms of anthrax and some kind of septicæmia), such testing has been accomplished, with the result of demonstrating these parasitic growths to be the *vera causa* of disease."

In an appendix Dr. Carter gives an account of his experimental inoculation of spirillum fever in the monkey, some culture experiments, and concurrent fevers at Bombay, chiefly remittent and typhoid. A large number of temperature-charts are given illustrative of the different modifications of the disease.

Although we have but cursorily glanced through this work, it is not because we deem it other than one of the most original and valuable contributions to medicine that has appeared of late years. The pages are full of facts personally observed by the author, and the conclusions he derives from these are drawn up with the caution and pains so characteristic of all his work. The appearance of such a

monograph as this adds to the obligations which medical science already owes to the earnest band of inquirers who have done so much to advance our knowledge of fevers in India, whilst it will also do much to stimulate research into the intimate pathology of the fever of which it treats, and of allied specific diseases.

The Surgical Treatment of Hæmorrhoids. By WALTER WHITEHEAD, F.R.C.S.E., Surgeon to the Manchester Royal Infirmary. London: J. & A. Churchill. 1882.—Mr. Walter Whitehead has published, in a separate form, his paper on the Surgical Treatment of Hæmorrhoids. His mode of operating is, after clearing out the bowels thoroughly by repeated enemata, and with the patient fully anæsthetized, to begin the operation by paralyzing the sphincter ani by stretching and massage; each pile to be removed is then seized with a forceps, and the mucous membrane dissected from its pedicle; the pile is then left attached to the rectum by its bloodvessels and submucous tissue only; this pedicle is then twisted through, the torsion being relied upon to close the vessels. The little flap of mucous membrane that is left is then stitched with fine catgut to the verge of the anus. It is urged in favor of this operation that it is precise, removing the whole pile and nothing more, that no open wound is left, and that it is easy and quite safe.

First Aid to the Injured: Five Ambulance Lectures. By Dr. FRIEDRICH ESMARCH, Professor of Surgery at the University of Kiel. Translated from the German by H.R.H. Princess Christian. London: Smith, Elder, & Co. 1882.—This is a far more attractive-looking little manual than that published by the Order of St. John of Jerusalem. It is printed on good paper, nicely bound, and the few illustrations are well executed. But it does not contain so much nor such exact information as its little black rival. The part that strikes us as being best done is the last lecture on transport, in which the instructions are plain and simple. In some other places too much space is devoted to a description of what the surgeon will do, and what therefore the reader is not to do, and is quite out of place. Many details which are necessary are entirely omitted: for example, in speaking of the temporary treatment of a fracture, the materials out of which splints and bandages to fasten them on are enumerated, but there is no hint of how long or how wide the splints should be, nor as to where they should be fastened. For burns a mixture of carbolic acid and oil is one of the dressings recommended, but we do not read that it is desirable to add any particular proportion of acid to the oil. But these criticisms merely indicate how difficult it is for even a very eminent surgeon and experienced lecturer to impart the desired amount of knowledge in five ambulance lectures. Her Royal Highness has, however, furnished the numerous pupils of these ambulance lectures with a very pleasant, readable manual which contains a great deal of useful information imparted clearly and well.

A Manual of Instructions for Stretcher Bearers. By Dr. G. A. RUEHLEMAN, Surgeon-Major, Saxon Army Medical Corps. Leipzig: Alfred Lorenty. 1882.—This is a small album of twenty-five plates, originally prepared for the Imperial German Army, but now published in several languages. The first plate gives a view of the skeleton, the position of the main arteries and most important viscera, which is by no means accurate; thus the bifurcation of the aorta is placed opposite the second instead of the fourth lumbar vertebra; the femoral artery at the groin is shown close to the outer side of the

pubic spine; and the brachial artery is shown dividing into the radial and ulnar above, instead of below the elbow joint. The following plates show simple and ready means of applying pressure to control hæmorrhage; the various modes of applying the triangular bandage, and temporary splints of all kinds; the different plans of lifting and carrying wounded persons; the ways of extemporizing stretchers and ambulances, and the Silvester method of performing artificial respiration. The text does not give any directions, so that the album is only of service in refreshing the memory of those who have been previously practically instructed, but for this purpose it is well adapted, as the drawings, with the single exception we have already pointed out, are admirably done.

Medical Annotations.

"Ne quid nimis."

THE TREATMENT OF ENLARGEMENT OF THE SPLEEN.

INJECTION of drugs into the substance of the spleen has been lately tried as a means of obtaining a reduction of the bulk of the organ in cases of hypertrophy. Hammond obtained a rapid reduction in size by the injection of ergot. Kusmaul, of Strasburg, endeavored to lessen the size of the organ by simple puncture with a large needle, hoping thus to produce a hæmorrhagic infarct which might cause atrophic shrinking, and by repetitions of the process a considerable reduction in size of the organ. The result, however, disappointed his expectation, for no marked effect was produced by fourteen punctures. Galvano-puncture was tried four times, with no better result. A parenchymatous injection of .1 gramme of sclerotic acid was made, and death followed in six hours. At the autopsy, no trace of hæmorrhagic infarct could be found in the organ; only around one of the punctures was there a reddish zone. The patient was suffering from leucocythæmia, and, whether death was caused by the sclerotic acid or not, the lesson is certainly taught that injections should be made into the substance of the spleen in that disease with extreme caution. Mosler, of Greifswald, has tried injections in other forms of enlargement with success, but prefers Fowler's solution to ergot, and has found those cases most suitable in which the spleen is hard. He thinks it well also, to apply ice to the splenic region for some hours before an injection is given. A remarkably good result has been reported by a St. Louis physician, Dr. Emanuel, of the internal use of ergot. The patient was a gentleman forty-three years of age, whose spleen was so much enlarged as to fill almost the whole of the abdominal cavity. It was firm and tender, and the patient affirmed that the swelling had existed for two weeks only. There was no history of malarial disease. Thirty drops of Squibb's extract of ergot were given three times a day, and the dose gradually increased to sixty drops. In three days the spleen had lost much of its hardness, although its size remained nearly the same. A week later, however, it was distinctly smaller; every day the diminution went on, and in a few days more the spleen was reduced to nearly the normal size.

THE PROTECTIVE POWER OF VACCINATION.

ANTI-VACCINATIONISTS have been desirous to find in the interesting quarrel which is now going on in Switzerland between the Cantons and the Fed-

eral Council evidence of the growth of an increased objection not only to compulsory vaccination, but to vaccination itself. It has, however, been clearly shown that the dispute which has arisen has really no reference to vaccination at all, but is simply an unwillingness on the part of the Cantons to allow the Federal Council to legislate on subjects which have until recently been solely under the control of individual Cantons. There is, therefore, nothing in recent events in Switzerland to lead to the belief that vaccination is less valued than formerly. That public opinion should not be equally strong upon this or any other subject in every part of Switzerland or England is no matter for surprise, but the question of the extent to which individuals are protected against small-pox is one which does not alone concern the particular town in which they are resident, and cannot therefore in our country, where the railway gives such ample opportunity for the communication between one town and another, be wholly entrusted to local authorities. A correspondent, Dr. Mitchell, writing from Meudon, in France, urges that the real issue involved in the difference of public opinion with regard to vaccination is, whether vaccination really protects, and he offers to join in an experiment by which he and an unvaccinated person shall submit to the inoculation of small-pox. In a letter to *The Times* some two years ago, Dr. Cory pointed out that this was the simplest way of proving by direct experiment the amount of protection afforded by vaccination. There are legal difficulties in the way of intentionally carrying out this proceeding in England, but the unintentional inoculation with small-pox matter of vaccinated attendants in small-pox hospitals is a matter of daily occurrence; and although an occasional local abscess is produced, the fact that these people escape small-pox is well known. It can hardly be expected that people who are unwilling to accept this evidence, which is constantly before their eyes, will be convinced by other experiment, however definite in character it may be.

THE GERMAN APOTHECARIES' CONGRESS.

THE Union of German Apothecaries numbers 2,755 members, who are distributed throughout all parts of the empire, and who have in most cases, for local purposes, their own separate organizations affiliated to the central body. This Union was held at Berlin during the month of September, being its eleventh annual congress. Amongst the matters of interest brought forward was the action which has been taken by the Mecklenburg Apothecaries' Union in conjunction with the Mecklenburg Medical Society for the purpose of restraining the sale of advertised specifics. Reference was made to the new edition of the *Pharmacopœia Germanica*, which contains many changes as compared with older editions; a work is in preparation which will give a summary of these changes. Professor Reichardt, of Jena, furnished some interesting details as to volumetric analysis according to Gay Lussac's system, with special reference to the testing of preparations connected with pharmaceutical chemistry. He remarked that volumetric analysis combines the use of measures with chemical analysis, and has certain advantages over analysis by weight, from the fact that it does not depend upon the exactness of the scale and the skill of the analyzer, but upon the visibility of a reaction much more easily observable than is the case with other methods. The funds of the Union amount to about £13,000. There are thirty stipends of £7 10s. per annum granted from the pension fund, and an extension of the pension list from another branch of the revenue of the Union

is in contemplation. Out of the general fund for the maintenance of the families of deceased apothecaries the estimated annual grants for 1883 are 100 in number, amounting in the aggregate to £600. The question of the employment of persons without any pharmaceutical training as salesmen in chemists' establishments was discussed, with reference to the regulations introduced this year by the Government of Saxony. It was agreed that such a step was both unnecessary and unadvisable in the interests of the safe exercise of the apothecary's calling, and that if adopted it would lead to further evils by the fact that persons would be introduced into the calling who might afterwards be found injurious to it. Dr. Tschirch read a paper upon micro-chemical methods of reaction in the service of technical microscopy. Dr. von Waldheim, of Vienna, reported upon the progress which has been made in the preparation of a *Universal Pharmacopœia*. An international commission of thirty-two delegates (from Europe and America) has been engaged in the task. Its object is the publication of the formulæ of those simple and compound medicinal substances respecting which, on account of the potent nature of their component parts, it is in the interest of the public that when prescribed by a physician of any country they should be dispensed of the same quality and strength by any apothecary in the civilized world. The questions of deodorization and disinfection were discussed by Dr. Franke, of Charlottenburg, in an exhaustive paper, which completed the programme. Weisbaden was chosen for the next annual congress.

MICROCOCCI IN MEASLES

WE mentioned a few weeks ago the purport of a paper lately read by Dr. Keating before the Royal College of Physicians of Philadelphia on the above subject. The full text of the paper has been published in the *Philadelphia Medical Times*, and the interest of the subject should be sufficient apology for dealing with it again. It may, however, be remarked that four years ago Drs. Braidwood and Vacher communicated to the Pathological Society of London a paper upon the same subject, in which they described highly refractile spherical bodies in the breath of measles patients, and similar bodies, together with rod-shaped, fusiform and ovoid forms, in the corium, lungs, and liver. They pointed out the resemblance of these bodies to the vaccinia-micrococcus, and referred to some earlier work by Hallier and G. Simon in the same line. At the time, if memory serves us aright, these observations of Braidwood and Vacher were not followed up, and, perhaps owing to the fact that bacterial pathology was then less in vogue, were not much accepted. Dr. Keating's research seems, however, to substantiate their facts, although he limits his microscopical investigations to the blood. These investigations were made by Dr. Furniss, who had previously carried out a similar research in diphtheria, in association with Dr. H. C. Wood. The blood was examined daily and micrococci were found in the malignant cases only, not in those of a mild type. Dr. Keating gives notes of eight cases, all but one of which were fatal. The blood was examined after death in most of the cases, and micrococci were found not only in the liquor sanguinis, but also in the substance of the white corpuscles. In some of the cases notes are recorded of observations made on the blood during life nearly every day. In the fatal cases death occurred from cardiac thrombosis and pulmonary congestion, attributed to clogging of the capillaries by the micrococci and the destruction of the corpuscles. Believing that in this fatal

type of the disease the condition is one of blood-poisoning, and that the occurrence of micrococci can thereby be explained as resembling that found in erysipelas, puerperal septicæmia, and diphtheria. Dr. Keating sought for the most active germicides as a basis of treatment. In brief, alcohol in large doses (it was given in the form of whisky) was found to be most efficacious, and its employment was suggested by its known action in checking the development of micrococci in culture solutions.

CHLOROFORM CATASTROPHES.

Two fatal accidents in the administration of chloroform have recently been added to the list of the lamentable records of chloroform catastrophes. They were very different in character, and one of them ought not, in fairness, to be attributed entirely to the anæsthesia. This was the case of James Butterworth, who as (the inquest held on him on September 2nd showed) was admitted into St. Bartholomew's Hospital with fracture of the jaw. Death occurred during the administration of the chloroform, but at the post-mortem it was found that the larynx had been injured, and that there was extravasation at the base of the tongue, and accumulation of blood in the trachea. In the second case the death occurred at the London Hospital on September 4th, also during administration. In this instance cancer of the tongue was the disease for which the operation was intended. The death in the first of these cases was evidently largely due to asphyxia, and we should be inclined to excuse chloroform as the destroying agent, while we should admit that for the particular operation it was a better agent than ether. In the second case the phenomena were those purely of chloroform death during the stage of excitement and muscular contraction. There were the usual sudden arrest of the heart, lividity of the face, cardiac apnoea, and collapse.

A POISON FOR TUBERCULAR BACTERIA.

A PAPER was recently communicated to the Paris Académie des Sciences, by M. de Korab, on the action of helenine on the bacteria of tuberculosis. The facts mentioned deserve notice, although we fear that the hopes suggested are too bright to be realized. The bacilli were cultivated in bovine blood serum, which was daily heated for a week to effectually sterilize it, and was then coagulated by a temperature of 65° C. A guinea-pig having been rendered tubercular by inoculation and inhalation, small tubercle masses were taken from it, introduced into ten tubes containing the tubercular serum, and the tubes plugged after some helenine had been poured into three of the tubes. All were kept at a temperature of 37° C. for a week, and at the end of that time inoculation experiments showed that the organism in the tubes to which the helenine had been added no longer caused tuberculosis, which was readily produced by the contents of the other tubes.

THE CURE OF HÆMORRHOIDS BY CARBOLIC ACID INJECTIONS.

At a recent discussion at the New York Clinical Society on the Treatment of Hæmorrhoids, Dr. C. B. Kelsey referred to his experience with injections of carbolic acid. He uses a solution of one part of pure carbolic acid in six and a half parts each of water and glycerine, and of this he injects about five drops into each hæmorrhoidal tumour. For the operation no anæsthetic is required, and the subsequent pain is said to be very slight. In

one case in which he used a solution of double strength each pile sloughed, and in another case, treated by one of his colleagues, Dr. Kelsey saw extensive ulceration caused, but this he attributes to want of skill in the manipulation. He has usually repeated the injections at an interval of about a week, so as to see the full effect of each injection before making another, and in this way the treatment may extend over months, but as it is painless and does not necessitate rest or even the abandonment of ordinary work, this is not a serious objection to the plan in many cases. This method of treatment, when carefully carried out, appears then to be safe, efficient, nearly, if not quite, painless, and not requiring rest or special nursing. It may be useful, therefore, where for any reason the ligature or clamp operation cannot be performed, and especially where it is important not to lay the patient up during treatment.

SUDAMINA IN TYPHOID.

M. ALBERT ROBIN has examined the liquid of sudamina in a case of typhoid fever, in which the eruption was so abundant that the vesicles were confluent, and formed bullæ of considerable size, some of them being as much as a centimetre in diameter. More than three grammes of liquid were collected from them. It was transparent and colorless, but on standing, a deposit formed, consisting of whitish flocculi, and at the same time the liquid became opalescent. It had a slightly acid reaction, and a strong, unpleasant odor. The microscope showed only a number of fine globules of fat and some epidermic cells. It contained neither albumen nor sugar, and was not rendered opaque by the addition of alcohol. No uric acid could be discovered in it by the murexide test. An analysis showed that it contained a considerable quantity of chlorides, but no trace of sulphates or phosphates: the proportion of water was 982, of solid matter 18, per 1,000; the solids consisting of 14 parts of organic and 4 of inorganic substances. Hence the amount of organic material eliminated by the perspiration in typhoid must be regarded as considerable.

EDUCATION BASED ON THE LAWS OF HEREDITY.

ATTENTION has been recently directed—notably in a little book entitled "Youth; its Care and Culture"—to the wisdom of basing education on the laws of heredity. This is something more than a mere recognition of what are called "physiological principles." If that term, as commonly used and understood, expressed all it actually implies, there would be no need to amplify its import. Mind is brain-function, just as locomotion is one form of muscle-function. The brain, when it acts, thinks and reasons, and judges and forms purposes. As the size, weight, form, and development of the bony skeleton, with its muscular apparatus, determine the limits and nature of physical power and activity, so do the size, weight, form, and development of the brain, with its apparatus of sense-organs, determine the limits and nature of intellectual power and activity; and as the personal characteristics of the physique are in great part inherited, in like manner the personal characteristics of mind are handed down from parent to child, so that the mental and moral qualities offering themselves for culture by processes which are, in the true sense of the word, *educational* in any individual, are the sum, or the resultant, of the aggregate qualities of the two parents, *plus* the influence of congenital conditions and immediately surrounding circumstances. It is essential to recognize this initial fact, and so to

order and apply the processes of education as to develop the good and repress the evil elements in the inherited character. Education ought to be individual and to comprehend a complete system of influences and processes adapted to the cultivation of the physical and mental nature in its concrete form and potentiality. There can be no greater or more ignorant blunder than to regard education as *teaching*. "Training" is a better term to use than teaching, but education in its full and practical sense means much more than both the ideas indicated by these two terms; it implies *improvement*, and "improvement, as applied to the compound organism, the physical and mental nature of man, must include the essential processes of culture, planting or grafting, uprooting or pruning, and growth-stimulation and training. Unless this threefold purpose of education—employing that term in its comprehensive and only true sense—is fulfilled, genuine improvement is impossible, whether consciousness strive to improve self, or others labor to nurture and train it. This is true of both body and mind, subject to the mutual relations which exist between these two parts of man's nature, if, indeed, they are separate. Every child born into the world is charged with potential energies that need to be stimulated, and with some which, in the interests of individual happiness and social expediency, it is necessary to eliminate, or, at least, repress." This being so, two consequences must be seen to ensue. First, to be really effectual, each child in a school or family should be trained and taught in a manner and upon principles peculiar to himself or herself, and not by a common method or to a common pattern. Second, the surroundings of child-life, the influences brought to bear upon it, the tasks imposed, the exercises body and mind are required to perform, the food with which they are severally fed, and the *régime* to which they are subjected, ought to be carefully selected and graduated to the individual nature and its special needs. If only a tithe of the truth about education were clearly understood, it would be seen that the care of the young is not only a responsible duty, but one which calls for special knowledge, rare sagacity, and exceptional skill.

HÆMORRHAGE AFTER EXCISION OF THE TONSIL.

THE removal of an hypertrophied tonsil is a frequent and simple surgical operation, in connection with which any complication is so infrequent as to be unheeded by many operators. Experience abundantly proves, however, that it is not unattended with danger from hæmorrhage, one of the most serious features of which is that it may not be primary but intermediary, or what is usually spoken of incorrectly as "secondary." There may be only the usual slight amount of hæmorrhage at the time, and then some hours later a profuse flow of blood occurs. This fact it is which gives additional import to the complication. Dr. Lefferts, of New York, has recently drawn attention to this subject, and has recorded cases in which the bleeding has been profuse, and discussed the appropriate treatment. In this country, we believe it is a not infrequent plan to give every patient an astringent powder to be moistened with water and introduced into the back of the throat should bleeding come on. Dr. Weir has recently recorded a case of this intermediary hæmorrhage, which illustrates well one cause of it, and the explanation of its mode of occurrence. One tonsil of a young man was removed with a guillotine; there was slight hæmorrhage at the time, but several hours afterwards, severe loss of blood—estimated at a pint—ensued, which was controlled by the application of per-

sulphate of iron and by pressure; the bleeding recurred twice subsequently. When Dr. Weir saw the patient he found that the bleeding vessel was an artery in the anterior pillar of the fauces. The vessels of the tonsils are small and lie in soft tissue, which readily permits of their natural closure when severed, and the various movements of the throat do not of themselves disturb the wounded vessels. Not so is it with the palatine arteries; they are, in the first place, larger, and, as they lie in the muscular tissue of the palate, when wounded they are constantly exposed to disturbance from the contractions of the palate muscles in deglutition. If one of these vessels be wounded then, in the operation of excising the tonsil, not only is the hæmorrhage freer than from the tonsillar vessels, but there is a great tendency to recurrent bleeding from the constant movements to which the wounded vessel is exposed.

THE MILK OF INTEMPERATE MOTHERS.

WE have lately received a letter from a correspondent, who stated that at a "blue ribbon" meeting (for women only), a working man's wife said that she was present at a similar assembly a short time before, in the course of which a physician, by way of proving to the nursing mothers present the injurious effect of intemperance on their offspring, left the room and presently returned with a sample of milk drawn from the breast of a drunken woman, to which he then applied a light, the result being that the milk burnt for five seconds. Our correspondent, who signed herself "Incredulous," asked if this were possible, and although we had no hesitation in answering in the negative, the question raises several very interesting issues. First, as to the presence or absence of alcohol in normal human milk. It is of course well known that koumiss is an alcoholic liquor prepared from milk by vinous fermentation of the lactose; the change is a slow one, lactose being of all sugars the least susceptible of fermentation. In the milk of the cow and ass, even when freshly drawn, alcohol was found by Béchamp, the alcohol increasing if the milk was allowed to set. This of course suggests the same origin for the alcohol as in the case of koumiss. With regard to human milk, the presence of alcohol, even if found, would suggest a similar explanation, but its presence has never been proved. Still, the wife of the working man is not the first person who has made assertions as to the alcoholic milk of alcoholic mothers. On examination, however, these assertions are seen to be founded not on chemical analysis, but on statements as to the effects of the milk on the infant. In an adult these would of course consist of exhilaration, followed by swimming eyes, inarticulate speech, unsteady gait, "dyskinesia" (uterine, no doubt, in female children,) and even inability to stand. We may observe many, if not all, of these symptoms in most infants at the breast; and, indeed, in this way the inability to recognize one's own father might be taken as evidence of double vision. Is, then, the whole infant population to be regarded as more or less permanently drunk? Again, evidence may be obtained from the remoter effects of alcohol. We have heard a story of a child who died of cirrhosis of the liver from the prolonged exhibition of steel wine; but we may safely affirm that if even a trace of the alcohol constantly imbibed by a large proportion of nursing mothers were to find its way into their milk, specimens of infantile cirrhosis would be far from rare. On the other hand, there is no doubt that some of the alcohol of alcoholic mothers not unfrequently finds its way into the system of their infants by a more direct route than the milk. Set-

ting aside, therefore, the question of alcoholic human milk as contrary to fact, one question still remains—namely, that of the general effects of alcoholic drinks on the milk of nursing women. To this question no short answer can be given. It may be stated at once, that the diet which ensures the best state of health and nutrition also ensures the best milk, but that no hard-and-fast rule can be laid down on the subject. Overfeeding as well as underfeeding, will often impair both the quality and quantity of the milk. It is, however, as in so many other questions, highly unscientific to lump all alcoholic drinks together, seeing that in those most generally useful, the alcohol is by no means the principal ingredient. To put gin and mild beer and claret together is to collect strange companions, who have, indeed, a common property, but little more. We are, however, within the mark in saying that, special medicinal questions apart, no nursing woman should drink spirits; that the less stimulant she can take (consistently with good health) the better; but it is no less true that in mild malt liquors, and especially in sound porter and stout apparently from the special preparation of the malt, we have a very simple and excellent stimulant to the lacteal secretion in many cases where it flags, and even in some cases where malt alone or other stimulants have failed. Of the impoverishment of the milk of women whose health is impaired by drinking there can be no reasonable doubt, and too much can hardly be stated in this respect. We quite agree with the blue ribbon orator so far as this, that if all nursing mothers were teetotallers it would be far better for the totality of British babies. In saying this, however, we must add that some infants would, in our opinion, be the worse; but that on the principle of "the greatest good for the greatest number," more would be benefited than injured. If only these nursing mothers took stimulants whose health was really improved by them, it would be better still. There are facts which seem to show that alcoholism produces in some women a functional or temporary sterility. On this question, being beside our present subject, and also as not unlikely to serve as an incentive, or at least an excuse, for intemperance, we will not enter. Is it not somewhat of an irony of fate that the teetotal cow and ass should produce alcoholic milk, while the alcoholic human female produces none?

Correspondence.

Audi alteram partem."

AN AMERICAN CONVALESCENT HOME.

(From a Roaming Correspondent.)

THE first convalescent institution ever established for hospital purposes in America was opened on April 25th, 1882. It was founded by Miss Mary Russell, to whose devotion it owes much of its success. It is called the Waverley Convalescent Home, and is worked by the trustees of the Massachusetts General Hospital. Waverley is about seven miles from Boston, the country around is hilly and well wooded, and the site selected for the convalescent home is a singularly beautiful spot. With all the progressive genius for which the Americans are famed, for some unexplained reason they have not heretofore recognized the advantages of convalescent hospitals. I shall have

more to say of the Massachusetts General Hospital on another occasion, and so need not refer further to it here. The Waverley Convalescent Home has been erected from a fund of \$100,000, which was specially raised for this purpose, \$30,000 being spent on the buildings and furniture, and \$70,000 being invested as an endowment fund for the permanent maintenance of the Home. It contains thirty beds for patients, and has two wards of nine beds each, one with three beds, two with two beds, and four single-bedded rooms. The Home is intended mainly for the use of the patients at the Massachusetts General Hospital, and both free and paying patients may be admitted. The proportion of accommodation for paying to free patients is about one to five; but as the object of the trustees is first to benefit the poor who are unable to pay the expense of procuring fresh air and change, so far none but free patients have been received. This is remarkable, and shows how easily the combined pay and free system works in the general hospitals of America. Although the majority of the patients treated in the Massachusetts General Hospital pay something towards the cost of their maintenance during their residence within its walls, the trustees enact that the Convalescent Home shall be for the minority—i.e., the poor; no pay patient is admitted, and no difficulty whatever arises. The whole arrangements at the Waverley Home are admirable, and the cheerful and cleanly appearance of everything fills the visitor with gratification. Every ward, every room, every office, from roof to basement, is admirably arranged and perfectly kept. Indeed, I have never seen a more model institution than the Waverley Convalescent Home.

The sanitary arrangements have been very carefully planned. The w.c.'s and slop-sinks are on a new and very simple but excellent plan, and might with advantage be introduced into English hospitals. The closet consists of a simple glazed earthenware hopper fixed upon an S-pipe placed upon a floor of glazed white tiles. No wood-work whatever is used except the seat, two seats being fixed with hinges, one on each side of the pan, so that the same closet serves for nurses and patients. The nurses' lid is raised, fixed to the side, and locked, except when in use. The slop-sinks are large and of galvanized iron, being two feet in diameter at the top, so that they serve as urinals when necessary; they are also fixed on a tiled floor. The partitions between the closets are of wood; they are placed six inches above the floor, the doors to the closets being one foot above the floor at the bottom and louvered throughout. Thus all parts of the closets and lavatories can be washed out with ease, there is no accumulation of dust or dirt, and all pipes are exposed. The woodwork and doors throughout the home are of pitch pine varnished, and the furniture is made of the same wood. This, the first American convalescent home, is well worth a visit, and I have little doubt many others will soon be erected. The plans and arrangements reflect great credit upon Dr. Whittemore, the able superintendent of the Massachusetts General Hospital, whose knowledge of hospital administration and the zeal with which he enters into his work must prove invaluable to the trustees.

GONORRHOEA.

To the Editor of THE LANCET.

SIR—I trust you will find space for the following remarks in your valuable journal.

Gonorrhoea is such a common and important disease that we must all feel glad that attention is at last being directed to it. The results are often

so disastrous and the complications so many that it is high time we tried to obtain some more definite cure than we have at present at command. I find by reference to notes and inquiries amongst other medical men that 75 per cent. of adult males have had it once; 40 per cent., twice; 15 per cent., three or more times. I find that the average duration is about nine months varying from eight days to four years. No two medical men treat their cases in the same way, but most of them agree that the duration of the disease is long, and the treatment very unsatisfactory. The disease seems to be greatly on the increase, and the older practitioners say that it is becoming more virulent. Could not some inquiry be made into the whole theory and treatment of this dangerous disease? If the treatment so strongly advocated by "M.R.C.S. Eng." is found to be satisfactory, the thanks of the profession will be due to him for bringing under its notice so valuable a remedy. In conclusion, I should like to ask "M.R.C.S. Eng." to give fuller particulars, so that a fair trial may be given. I remain, Sir yours, etc.,

C. H. W.

Sept. 18th, 1882.

P.S.—While on the subject, I should like ask whether gleet is contagious or not?

"THE USE OF THE FORCEPS IN MIDWIFERY."

To the Editor of THE LANCET.

SIR—I am not all addicted to the use of instruments where they can possibly be avoided; yet I find, on referring to my obstetric list, that of the last 400 cases attended by me, the forceps were used 12 times—i.e., 8 times in primiparæ and 4 times in multiparæ, or an average of about 1 in 33. I think it likely that half these cases might have been terminated without the use of forceps had I felt myself justified in exposing the poor women to several hours' further unnecessary agony; but I may say that I make it a rule of practice not to wait more than three hours when there is no advance in the second stage of labour.

I disapprove as much as anyone of meddlesome midwifery, and can scarcely believe that in a run of several hundred consecutive cases it can ever be necessary or desirable to employ the forceps in so many cases as 1 in 8—the proportion in which they are said to have been employed by the late Master of the Rotunda.

I am, Sir, yours faithfully,

B. A. RUGG.

Wood Green, Oct. 9th, 1882.

"HAMAMELIS VIRGINICA."

To the Editor of THE LANCET.

SIR—I cannot give your correspondent, "C.," any information regarding the tincture of hamamelis, not having used it; but I can speak most highly of hazeline, the active principle of the witch hazel. I have prescribed hazeline as an injection (twice daily) in several cases of hæmorrhoids with most satisfactory results, relieving cases that had resisted all other treatment. It does not cause pain; on the contrary, relieves all unpleasant symptoms.

Hazeline was highly recommended two years ago for cases of hæmoptysis, epistaxis, melæna, etc.; but administered internally it has disappointed me in such cases. As a local application I have never known it fail, and I consider it invaluable as such in the treatment of indolent and varicose ulcers, etc. Injected into the nostrils in that common

complaint, "cold in the head," it gives immediate relief.

While the correspondence on the "abortive treatment of gonorrhœa" was being carried on in THE LANCET I had opportunity of using hazeline as an injection in a case of "old gleet," and was agreeably surprised to find that, after a few injections, my patient was cured. I also had the opportunity of using it in the early stage of gonorrhœa, and with good result; and I believe that if any of your readers who may have more opportunity should give the drug a fair trial they will not be disappointed with the "abortive treatment of hazeline" when using hazeline as an injection. A glass syringe should be used; metals decompose hazeline.

I am, Sir, yours truly,

W. S. STILES.

Chesterfield, Oct. 30th, 1882.

CASE OF IMPERFECT DEVELOPMENT.

To the Editor of THE LANCET.

SIR—The following case of imperfect development occurred in my practice last week, and as it appears of somewhat an unusual nature, I send you an account of the same. The original has been sent to the museum of the College of Surgeons. The placenta was attached to the upper part of the child's skull, and took the place of any bone in that situation, and also of any dura mater, as the portion of brain which protruded, owing to a rupture occurring during birth, was destitute of that membrane. There were no fingers on the left hand, only a thumb; and the left leg completely twisted outwards. The child was born before my arrival, and I found it crying strongly. Although it was evidently a case of partial placenta prævia, there seems to have been but very little hæmorrhage at the time, although a week before the patient appears to have lost considerably. The mother is the wife of a strolling actor, and is slightly deformed from old hip mischief.

I am, Sir, yours faithfully,

JOHN B. HARRIS.

Violet bank, Lower Norwood, Oct. 27th, 1882.

CASE SIMULATING HARE-LIP.

To the Editor of THE LANCET.

SIR—The following case may be deemed of sufficient interest for insertion in your pages.

Being called to see C. H.—, ten months old, on August 5th, about 12.30 p.m., I found a severe cut on the upper lip, extending through the septum of the nose right through the lip. This accident occurred as follows:—The foot of an iron bedstead went through the flooring of the bedroom and upset some ornaments that were on the mantelpiece close by. On examination I found that the wound was quite through, and sloping rather to the left side, and that she could take the breast very well. The wound was put together by means of two silver sutures, and adhesive plaster was applied to give it a better support. One suture, nearest to the nose, was removed on the tenth day; the other was left till the fifteenth day, when it was removed, and has left hardly a mark to be seen.

The points of interest in this case are—(1) there was very little hæmorrhage, (2) the child could suck all along, and (3) the rapid recovery.

I am, Sir, yours, etc.,

W. E. WILLIAMS.

Duylan, Oct., 1882.

THE OIL OF MALE FERN.

To the Editor of THE LANCET.

SIR—The question as to whether the oil of male fern is a poison when administered in small doses is one by no means devoid either of interest to the practitioner or of importance to the public. In my opinion it must be regarded as such, at least in the case of individuals of a certain temperament—viz, the nervous.

In 1856 I recommended a friend—a thin, spare man, possessed of extreme pallor of countenance, and aged about about twenty-three years—to make trial of the drug. He took but a single drachm, and that drachm followed, after the lapse of ten hours, by a tablespoonful of castor oil. The results were as follows:—Diarrhoea, nausea, vomiting, colonic spasms, and semi-collapse for about two days; nausea, a burning sensation at the epigastrium, and inability to stand erect for about a fortnight afterwards. A very slow and tedious convalescence. At this date—twenty-six years since taking the dose, please to recollect—the bare mention of the drug causes him to shudder, and to declare that he has still the smell of it remaining in his nose.

Was he not actually and veritably poisoned? Is he still, to some extent, suffering from the toxic influence of the medicine? Will he ever become perfectly free from that influence?

I am, Sir, yours faithfully,
JOHN BEADNELL GILL, M.D.

Canterbury, Nov. 1st, 1882.

TRACHEOTOMY TUBE.

To the Editor of THE LANCET.

SIR—Will you kindly allow me to draw the attention of the profession in your columns to a new tracheotomy tube which Messrs. Maw, Son & Thompson have manufactured for me. It is made of the new material, celluloid, is cleanly, light, and very smooth, and possesses a quality which is not found in india-rubber or metal—viz, the property of being readily moulded by immersion in hot water to any shape required.

Having recently performed tracheotomy in a case of malignant disease of the oesophagus, I found that the growth was pressing upon the trachea to such a degree that the india-rubber tubes became flattened. It occurred to me that a tube made of celluloid would be sufficiently firm to resist any pressure from without, and the result has so justified my expectations that I can confidently recommend them to the profession.

I am, Sir, yours faithfully,
F. KING GREEN, F.R.C.S.

Guy-street, Bath, Nov. 7th, 1882.

ON THE INTERNAL ADMINISTRATION OF CHRYSOPHANIC ACID IN PSORIASIS.

To the Editor of THE LANCET.

SIR—Since the publication of Dr. Napier's interesting article on the above subject, which appeared in your columns recently, I have given this drug an extensive trial, and have been remarkably struck with the result.

In the first case in which I tried it its action proved so rapid and effective that I think it worthy of record in connection with the other cases that have been brought forward. A young, delicate lad, fourteen years of age, came to me with well-marked psoriasis of five years' standing. The abdomen and chest were covered with numerous rings

about the size of a florin. The upper and lower extremities were also affected; the patches were here, however, much smaller and less numerous. I ordered him one-fifth of a grain of the acid three times a day in sugar of milk, with directions to take the powders about half an hour after meals. No external application of any kind was given. I saw him the following week. Some of the patches were beginning to fade, whilst a few had actually disappeared. The following week those on the chest had entirely died away; the others were fading quickly, especially those on the belly. At the end of the third week he was practically cured, only a few small spots remaining on the arms and legs. He continued the medicine (one-tenth of a grain) for a month afterwards, and, as I have not seen him since, I conclude there has been no return. The dose (one-fifth of a grain) was not increased throughout. The boy never complained of any nausea or sickness, or any other ill-effects from the use of the drug, so common when larger doses are given.

I have tried it in several other cases with marked benefit, but not with such success as in the case mentioned. I have generally begun with one-fifth of a grain, and have rarely exceeded that amount, having found that where the smaller dose failed to do good a larger dose was equally ineffectual. I have also noted the fact that the disease is more amenable to treatment when occurring in strumous cachectic patients than in those of a stronger and healthier constitution.

I am, Sir, yours, etc.,
F. W. CLIFTON, M.R.C.S. Eng.
Easy-row, Birmingham, Oct. 31st, 1882.

"REMOVAL OF HAIR FROM THE FACE."

To the Editor of THE LANCET.

SIR—Your correspondent, "A Puzzled Practitioner," asks in a recent issue, "by what means he can permanently remove a patch of hair from a prominent position of a patient's face?" May I suggest the following a treatment, which I have seen very successful in several instances. It is applicable both for the removal of hair and moles.

A small cautery is necessary. It should be something of the following form:—From a small bone handle passes a stem of platinum-wire three inches long, curved at a right angle half an inch from the end, which resembles a blunt needle. At the angle is a bead-like bulb, which serves as a reservoir for the heat when in use. The bulb and point having been made white hot in the flame of a spirit-lamp, the affected skin (previously shaved) is to be deeply punctured by a number of stabs, close together, and over a space of about a sixpence. Repeated heatings of the cautery will be required, but the process is almost painless, and when the sore heals a white cicatrix will appear, free from pigmentation or hair bulbs. The same process can be repeated at subsequent sittings until the whole affected area is cured. I do not remember the name of the cautery or the maker, but I could easily procure these particulars should your correspondent desire it.

I am, Sir, yours, etc.,
Plymouth, Nov. 5th, 1882. G.C.

ENGLISH SPORTS.

To the Editor of THE LANCET.

SIR—The following report is extracted from the *Daily Telegraph* of Wednesday, Nov. 1st:—

"Catching the Stag.—Our Oswestry correspondent telegraphs: 'The annual sport of catching the stag to be hunted on the anniversary of the

Earl of Powis's birthday took place yesterday morning in Powis Castle-park, Welshpool. His lordship and a number of equestrians—ladies and gentlemen—were present, and a large field of pedestrians. The stag was pursued by men on horseback and on foot, but not by hounds. After an hour's pursuit the stag fell dead. His lordship gave another stag, which ran for about an hour up and down the park, and was ultimately taken in the net. The stag seemed somewhat distressed, and after his horns were cut off the fine animal died. This second fatality created a great sensation, and the hunt was at once abandoned."

Assuming the above to be true, it would be interesting to know whether his lordship and friends belong to the anti-vivisection party. I am surprised that such gross brutality is allowed in a country where vivisection, for possible and probable good to human kind, is guarded by most stringent laws, and which possess a Society for the Prevention of Cruelty to Animals. Without further comment on the apparent inconsistency of the law on the subject,

I am, Sir, yours obediently,

A. PHILLIPS HILLS.

Battersea-park, Nov. 3rd, 1882.

COMPRESSED AIR BATHS.

To the Editor of THE LANCET.

SIR—A patient of mine asked me for some information respecting the above. Can you or any of your readers tell me anything about them?

I am Sir, yours faithfully,

M.D.

Oct. 12th, 1882.

"* Compressed air baths are an old remedy, especially carried out at Reichenhall. They are apt to cause tinnitus aurium, pains in the ears, and headache. They slow the pulse; raise the arterial tension. They have been recommended in emphysema and whooping-cough. They are said to increase expectoration and excretion (Burdon-Sanderson in *Practitioner*, vol. i.). With only slightly compressed air the effects are mainly those of increased absorption of oxygen. Ducrocq, Waldenburg, Biedert, and Moutard-Martin have written on the subject.—ED. L.

URTICARIA AND MOSQUITO-BITES.

To the Editor of THE LANCET.

SIR—"L.R.C.P." asks for a suggestion as to the treatment of a case of urticaria. My experience of the subject being small, I feel the greatest diffidence in venturing upon an opinion, and only do so because no response has hitherto been forthcoming from more competent authorities. I read recently in a medical paper that Dr. Schwimmer treats urticaria by the internal administration of atropine. I cannot say that I have had the opportunity of verifying the efficacy of the remedy in the ordinary form of the affection, but I can testify to its value in the variety produced by the bites of gnats and mosquitos.

The past summer, notwithstanding the moderate degree of heat, has been remarkable in Paris for the number of these insects, and I for one have been severely visited by them. In my case each bite gives rise in the course of a few minutes to a raised white lump, which disappears after a variable time, leaving an irritable papule, lasting for

some days. I find that the application of a solution of atropine shortens the whole process, and instantly relieves the itching. The solution I have used is one part in a thousand.

"L.R.C.P." does not say what are the remedies he has employed. I take it that, with the exception of the sluggishness of the liver, all other likely sources of reflex irritation have been eliminated. Whether there be any gastro-intestinal disturbance or not, this condition of the liver might be benefited by a course of rhubarb and quinine. If all means of removing and allaying irritation fail, there still remains the possibility of inhibiting the morbid reflex by bromide of potassium; and if it comes to this, it would be well to associate it with arsenious acid.

I am, Sir, yours faithfully,

OSCAR JENNINGS, M.D.

Paris, August 31st, 1882.

A TACK IN THE EAR.

To the Editor of THE LANCET.

SIR—I presume the discovery of a carpet-tack in the external auditory meatus is not a very usual occurrence, and I therefore send a short note of the case.

A lady consulted me a few days ago for deafness and occasional throbbing in the right ear, and on examination with the ear-speculum I found a black mass on the bottom of the meatus. Being firmly imbedded in a mass of clotted blood, wax, and cotton-wool, it resisted all attempts at removal by the use of a large syringe and hot water; but by the aid of a small artery forceps and short hooks set in a handle, I succeeded in extracting a carpet-tack, head foremost. As the mass completely plugged up the meatus (in which it had been for years), it was very difficult to extract. She now hears perfectly.

I am, Sir, your obedient servant,

EDWARD HAUGHTON, M.D.

Spring-grove, Upper Norwood, S. E., Oct. 10th, 1882.

THE TREATMENT OF GONORRHOEA.

To the Editor of THE LANCET.

SIR—Some years ago, when this subject was under discussion in THE LANCET, I advanced the opinion that the most rational, and, consequently, most likely to be successful, mode of treatment was a local one, and gave the results obtained by it. Further experience has proved that those results, which were so favorable as to have their accuracy called in question, were not exceptional, and that the view upon which the treatment was based was correct.

I am, Sir, yours very faithfully,

PHILIP FOSTER.

Leeds, Oct. 17th, 1882.

HORSFORD'S ACID PHOSPHATE.—In preference to acid phos. dil. in general debility, Dr. O. A. Boothby, Philadelphia, Pa., says: "I have tried Horsford's Acid Phosphate in several cases of general debility, with faulty digestion, also in sick headache, and am much pleased with the results obtained. As far as my experience goes, your combination is far preferable to the ordinary dilute phosphoric acid."

Clinical Lecture

ON A CASE OF

MEDULLARY SARCOMA OF THE LIVER, RIGHT LUNG, AND HEART.

By DAVID DRUMMOND, M.A., M.D., T.C.D.,

Physician to, and Joint Lecturer on Clinical Medicine at, the
Newcastle-on-Tyne Infirmary.

GENTLEMEN—I take for my subject to-day the case of a patient whom you saw in the Bishop ward of the infirmary, and on whom you witnessed a necropsy a few days ago. He was a coal-miner, aged thirty-two, and of very intemperate habits. Ten weeks before admission, when in his usual health, he lay out all night in a drunken condition, exposed to rain and cold. The result of this exposure was an attack of shivering, followed by a "stitch" in his right side, and cough. He then sought advice, and was told he had "caught cold in his chest," for which he received medical treatment. Though ill, he continued to follow his employment, which he did for a fortnight subsequent to the initial attack, though evidently "against great odds," as the medical man, under whose care he afterwards came, wrote when he kindly supplied me with the early particulars of the case. He then was confined to bed; the pain in the right side became more severe; he complained also of pain in the abdomen (hypogastrium) and back; his cough increased; profuse perspiration occurred; and the expectoration which previously was mucopurulent, became sanguinolent in character. About this time he suffered much "from what seemed most like diaphragmatic cramp." (I quote from his doctor's notes.) The bowels were irregular, generally costive, and his appetite was very bad. Three weeks before admission the result of physical examination was as follows: "The right chest was dull on percussion to the spine of the scapula; the respiratory sounds were feeble, and without vocal resonance; dullness in front extended up to the nipple, this continued over the liver two fingers' breadth below the ribs." All this time he was emaciating rapidly. The case was regarded as "fluid in the chest, probably pus, which depressed a congested liver," which undoubtedly was the most obvious construction to put upon the data at that stage of the case.

(7)

When brought to the infirmary the patient looked exceedingly ill; he was markedly wasted, and his face wore a most anxious expression. He was unable to lie on the left side or on the back on account of the pain across the abdomen and back, which was always much increased in severity when he assumed either of those positions; it was especially painful for him to lie on his left side. He also complained of "shoulder-tip" pain, right and left. His favorite posture was on his hands and knees, with his head buried in the pillow; but it was also a relief to lie on the right side. When he assumed the dorsal decubitus, with the abdomen exposed, a tumour at once became apparent, which was evidently the liver. The right lobe, the sharp edge of which could be distinctly felt, reached down to the crest of the ilium; the left extended down to one centimetre below the umbilicus, and completely across the abdomen. On the surface, the organ (on admission) felt comparatively smooth, and, although firm, not what is generally termed hard. At the extreme border of the right lobe an indistinct nodule or two could be felt; but handling the liver caused so much pain that this method of examination was not pushed beyond what was considered necessary to elicit the few points already referred to. There was no ascites, nor was he in the slightest degree jaundiced. A short "hacking" cough attracted our attention to his chest. The right thorax was one centimetre larger than the left; the ribs were slightly separated, and the interspaces somewhat flattened. The side expanded very imperfectly, being almost still on the deepest inspiration. On percussion the side (right) was found to be absolutely dull posteriorly, conveying to the finger the sensation of marked resistance. Auscultation revealed the vocal and breath sounds to be notably diminished, such distant respiratory sounds as were present being evidently conducted from the opposite side. In front, also, the right chest was dull on percussion, the dullness extending across to the left parasternal line. Here the stethoscope revealed nothing beyond abnormal silence, the feeble sounds which were audible being conducted from the heart and bronchial tubes. The left lung appeared to be normal, for beyond puerile breathing, accompanied by a few râles, physical examination elicited nothing. The heart sounds were feeble, especially the first; there was no murmur. The apex beat was with great difficulty localized, but seemed to be in the left nipple line between the fifth and sixth ribs. The cardiac area of dullness

was not accurately mapped out, merging as it did into the right lung dullness. The patient suffered considerably from dyspnoea. There were no signs of pressure upon the large thoracic vessels, neither oedema nor superficial veins. The expectoration was distinctly of two kinds—viz., mucopurulent, and like red currant jelly (bloody). The urine was scanty, but beyond being loaded with "vermillion" urates, it was normal, containing no albumen. Our patient's appetite was excessively bad, indeed, he had a great dread of swallowing food, either liquid or solid, as the slightest distension of the stomach enhanced the pain beyond endurance; consequently, the only sustenance he received had to be administered per rectum. The perspirations were very profuse, especially about the face, neck, chest, and hands, the skin of the abdomen being generally dry and harsh. The temperature was, as a rule, sub-normal, ranging between 96° and 98° F. The diagnosis, those of you who saw the case will remember, was made of malignant disease of the liver and right lung—most probably encephaloid cancer. The grounds on which such a conclusion was founded were, as far as the lung was concerned, dullness, markedly increased resistance (solidity), absence of vocal and breath sounds, the knowledge that the pleural cavity did not contain fluid—for the patient had been tapped in a special hospital before admission into the infirmary, a little blood alone being drawn off, according to his wife's account—with the presence of disease in other organs (liver). And, as regards the liver, the last-named fact—i.e., extension of the disease—rapid progress of the case, and the existence of a painful, somewhat nodular, enlargement. The medullary form of cancer was chosen because of the rapidity of the increase, scirrhus being generally much slower in its advancement.

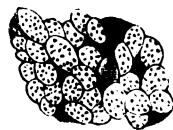

A few days after his admission it was observed that the nodules on the surface of the liver were much better marked than when the patient was first seen, especially was this the case on the edge of the right lobe, where the tubera, as the nodules of new growth are sometimes called, were distinguishable. It could be made out with ease that the whole organ had increased in size within a few days, the left lobe extending down to two centimetres below the umbilicus; on its surface also, at that date, nodules could be felt which distinctly changed the character of the hitherto almost smooth left lobe. It was thought desirable to try, if possible, to make the diagnosis more certain by ascertaining the description of cells of which the apparently new growth was made up; consequently, to this end, the hypodermic syringe was used, following the practice which you know is constantly adopted in the wards of the Newcastle Infirmary. And here I would take the opportunity of impressing upon your attention the utility of employing the hypodermic needle as a routine act in medical diagnosis; by its use you will often be saved from grave errors. One well-known physician remarked to me, in conversation upon this subject, that he had used the hypodermic syringe constantly for the past two years, ever since he had made a serious error, which probably could only have been avoided by the possession of such evidence as the needle could have furnished. As the patient—the subject of the present case—was getting hypodermic injections of morphia to relieve pain, I endeavored, as you will remember, to add as little as possible to his sufferings in pursuing the method of investigation of which I have just spoken; consequently, on one or two occasions, I administered the morphia immediately over the part of the liver I wished to puncture, and then, after a second or two had elapsed, I thrust the "needle" into the liver.

By this means, without causing any pain, I was enabled to draw off a few drops of fluid resembling pus, or cancer juice. My object in injecting morphia before puncturing was to guard against the risk of causing pain by groping about with the point of the needle, should the site at first selected be not a suitable one. The cells drawn off in this way were of two descriptions—the most numerous resembled pus cells very closely, there being also a few somewhat larger, irregular-shaped, cells, some oval and others almost caudate with a single nucleus. It was thought then that in the juice from the liver we had discovered pus and cells usually found in the alveoli of medullary carcinoma; though this view was somewhat shaken, especially as regards the pus, when a subsequent puncture into a part of the liver not nodular furnished dark blood which contained a number of the same small round cells. Microscopical examination of the sputum, which as before stated, contained blood, yielded no information of importance. The liver rapidly became more distinctly nodular. The harassing cough, almost constant retching and hiccough, severe pain, profuse perspirations, and inability to take food soon brought the patient exceedingly low, and he died ten days after admission, and eleven weeks from the commencement of the attack.

The post-mortem examination showed the body to be very markedly emaciated; there was no jaundice or anasarca. The cavities were free from fluid. The liver, which occupied nearly the whole of the abdominal cavity, weighed 9 lb.; it was adherent to the diaphragm, especially by the right lobe. The surface was studded with pale yellowish nodules, varying in size from a pin's head to a small orange, the larger of which were umbilicated,

Left auricle.

Lung.

a condition which you can see well yet. Though the specimens before you have been in spirit for some days these nodules are still quite soft, and when cut into, as, for example, when a section is made through the liver, a considerable quantity of "juice," evidently rich in cells, flows from the surface. The liver substance itself was exceedingly pale, but apparently comparatively little of it is free from the new growth. The right lung, which was adherent, is, as you see, completely solid, the greater portion of the consolidation being due to so-called "grey hepatization;" but a large mass of new growth, similar to that found in the liver, the size of a small coconut, embraces the root of the lung, and extends into its substance and down to the base, apparently infiltrating the pleura and diaphragm. The left auricle is also affected by the same growth, the extension having probably occurred along the pulmonary veins, which are surrounded and slightly compressed, the capacity of the auricle being reduced considerably. The left lung was congested, but otherwise normal. The kidneys, spleen, and pancreas were unchanged, though the latter was surrounded by a mass of diseased glands. The stomach presented no unusual appearances; in short, there was no other disease but that already described. Those of you who were present at the necropsy will recollect that the opinion was advanced, from the naked-eye appearances, that the disease was encephaloid

cancer. From the three sections (microscopical) which I have prepared from the heart, lung, and liver, you will see that that opinion was only correct in a limited sense, for the true structure of the growth is evidently sarcomatous, being composed of cells which resemble the small round-celled sarcoma, but with extremely little basement

Liver.

Isolated cells from liver.

substance; only here and there is it possible to discover any intercellular substance. The cells are not uniform, like the small round-celled sarcoma, but vary considerably in shape and size; at the same time they are all of one type, being from round to irregularly oval. They are also larger than the cells of the ordinary lympho-sarcoma; for example, when compared accurately with sections of glio-sarcoma and lympho-sarcoma (so called) the cells appeared nearly twice as large, though apparently not at all so large as the cells of the large round sarcoma.¹ In the section from the liver it will be noted that the growth has in certain parts taken on the appearance of encephaloid carcinoma, the cells being isolated by alveoli made up of delicate connective tissue, at the same time the greater part of the growth in the liver resembles the lung growth, but in the lung or heart no such arrangement can be found. In Wagner's "General Pathology" (translation) you will find the statement made that "transitions to medullary cancer (from round-celled sarcoma) arise." Other authorities allude to the coexistence of these two forms of disease. To the minute structure of the growth before us, differing slightly as it does from the "round-celled" sarcoma I have been unable to attach any other more accurately descriptive name than that of "medullary sarcoma." In its clinical history and microscopical appearances it approaches so closely to that of encephaloid cancer that it is impossible to distinguish the two. Had I made out the true character of the cells drawn off by the puncture from the liver it is possible the disease might have been more accurately diagnosed, but, using as I did a strange microscope with a low power, I mistook the round, and somewhat oval, cells for pus. I have said that the clinical features of this form of sarcoma resemble medullary cancer very closely; certain it is that the former at times is quite as malignant in its nature as the latter. Virchow remarks in his "Cellular Pathology" (Trans., second ed., p. 487) when speaking of sarcomata, "in many cases they occur throughout the whole body metastatically, to such an extent that scarcely any organ is spared by them." In the rapidity of the growth also is there a near resemblance; medullary cancer of the liver being generally of very short duration, a fatal termination occurring within a few months, or even weeks. Comparing my observations upon the case with those of the medical man who saw the case first, it would seem that in a period of about twenty days the liver extended from occupying a position "two fingers breadth" below the ribs down to the crest of the ilium. In-

deed, from what I have been able to gather both from the patient himself and from information kindly furnished by another medical man who saw him, and also taking into account his wife's version, the period during which the rapid growth took place must have been a very few days. I am inclined to view the growth in the liver as secondary to the lung, which in turn was secondary to the mediastinal glands and connective tissue. Primary growths of the malignant type being rare in either of these organs, especially before thirty-five or forty years of age. I am unable to advance any view as to the means by which this form of sarcoma might clinically be distinguished from encephaloid cancer unless it be by the recognition of the true nature of the cells drawn off by the hypodermic syringe. It is worthy of attention that, in spite of the manner in which the liver tissue was encroached upon and compressed by the new growth, there was no ascites. Effusion into the peritoneal cavity in cases of cancer of the liver does not occur, as a rule, as the result of venous obstruction in the liver, as in cirrhosis of the organ, but it generally depends upon a chronic peritonitis originating in the neighborhood of the diseased liver. At the autopsy we found the peritoneum remarkably free from disease. Ascites has been found to occur in about half of the cases, and jaundice, perhaps about as frequently; this latter symptom may be said only to be present when a cancerous nodule compresses the bile-duct in the liver, or when the duct is encroached upon by enlarged glands in the portal fissure; it is generally supposed to be characteristic of the jaundice of hepatic cancer that it continues to the end, having once occurred. The diagnosis of cancer in the lung is generally a matter of difficulty, especially where there are scattered nodules, in which case there may only be very slight alteration in the percussion and respiratory sounds. However, as primary cancer of the lung is extremely rare, it will often be found to be accompanied by mediastinal growth, from which the pulmonary affection has sprung, when there will be dulness extending across the sternum, which will either be due to aneurism, fluid, or tumour—consolidation of the lung almost never causing dulness, which extends across to the opposite side. Such was the case in our patient, and as neither aneurism nor fluid could be entertained, it was consequently supposed that a mediastinal tumour existed, which with the physical signs, dulness and diminished vocal and breath sounds, viewed in the light thrown upon the case by the discovery of the liver disease, led to the diagnosis of cancer of the lung. The diminution in the vocal and breath sounds depended of course upon occlusion of the bronchial tubes. Had the air passed to the lung—consolidated (grey hepatization) as it was—the difficulty must have been much increased. It is not at all unusual to find the lung infiltrated with caseous matter, where the root is affected by cancer. I recently made a post-mortem upon a case of cancer (scirrhus) of the penis, where this condition was well-marked in the left lung, secondary scirrhus deposit having attacked the root of the lung, and also the kidneys. I know of no means of recognizing cancer of the heart during life, though it often occurs when the new growth occupies the anterior mediastinum.

DR. GAILLARD THOMAS has, it is stated, consented to resume his occupancy of the chair of Gynecology at the College of Physicians and Surgeons, New York, with Dr. Charles S. Ward as chief clinical assistant.

Introductory Address

DELIVERED IN THE

UNIVERSITY OF GLASGOW,

To the Students of Medicine of the Session 1882-83.

By W. T. GAIRDNER, M.D.,

Professor of Medicine in the University, and Physician-in-Ordinary to the Queen in Scotland.

GENTLEMEN—I appear before you to-day at the request of my colleagues, not, certainly, without a feeling of satisfaction and even pleasure in my task, but also with a most serious sense of responsibility. Only on two previous occasions has it fallen to my lot to address to medical students the very first words of exhortation at the opening of a new session—once in Edinburgh, in 1856, and once in Glasgow, in this university, but not in these halls, in 1866. When we consider that sixteen years have elapsed since the last of these occasions, and that during this interval almost all of my then colleagues in the Medical Faculty have either been taken from us by death, or have passed into an honorable retirement, the very facts themselves seem to raise the question, Where shall we all be after another sixteen years? And although I am assuredly not bound to answer this question, and have no personal misgivings leading me to despair of being permitted to labor for some years to come on your behalf, yet it cannot but be present to my mind that this may be the last occasion for me, as it is the first for some of you, on which words like those I have it in my mind to speak may remain to be spoken between us. Let us, therefore, strive together to make the present occasion one which we may look back upon, if God will, as tending to confirm in us whatever of good, honest purpose we are conscious of having devoted to our work in the past; and not devoid, also, of some new inspirations or glimpses of insight as regards the unknown future that is before you, and equally before all of us, your teachers. I am sure that I speak the mind of all of them, when in welcoming you anew to these benches, we add the expression of an earnest desire, or prayer, that we may also be enabled to perform our share in the duty aright, and that the good work done and the friendly associations formed during the session of 1882-83 may be of such a nature as to be an abiding influence for good over all the years to come.

In considering the materials before me for a new Introductory Address, it is impossible to avoid looking back for a moment on these two former addresses. I would fain not absolutely repeat myself, and yet there is much of what falls to be spoken which could only be spoken again in similar, if not identical, words to those already used. It would not be altogether impossible, perhaps, to commit this justifiable plagiarism without a chance of detection on the present occasion. For introductory addresses are, like the occasions that give rise to them, soon forgotten, at least by all who are not immediately concerned in them. But I am not without hope that such reminiscences as cling to my own mind of these earlier addresses may be turned to account, not for the purpose of reproducing their ideas, but rather of inquiring how far the progress of the medical art has, in any degree, confirmed or controverted the impressions entertained of it by a teacher sixteen or twenty-six years ago. And with this view I intend, as soon as possible, perhaps in a few days, certainly some time between

now and Christmas, to place at your disposal the whole of these addresses, including the present, so that you may at your leisure, if so minded, follow out with more full understanding and appreciation the few suggestions, imperfectly expressed as I fear they will be, called forth by the present occasion.

And while in this retrospective mood, I am reminded that only the other day we had set before us, in the shape of a leader in *The Times*¹ and in connection with the opening this month of the various medical schools in London, a singularly clear and luminous appreciation of the changes introduced into medical study and practice in England, as the consequence of the Medical Act of 1858; from which anonymous, but not unauthoritative, statement it may be admissible to borrow a few sentences as an illustration of our present position; keeping in view always that the writer of the article in question, well informed and thoroughly impartial as regards his own division of the United Kingdom, has had England, and apparently England alone, in view, in describing the state of medical education before 1858, and the changes gradually effected, owing to the legislation of that year. Were one at liberty, indeed, to guess (for everyone knows we can do no more) at the authorship of that particular article, to see with the mind's eye the Vulcan that forged the thunderbolt of Jupiter on that particular morning, I should be disposed to say that, judging from internal evidence alone, the brain that guided the hand that wrote that particular article was also one of the most active of those recently at work in elaborating the Report of a Royal Commission appointed to inquire into the Medical Acts, with a view to their consolidation and amendment. If this be so, it gives, for us, an additional interest to the sentences of that article which I shall presently lay before you; and although it is by no means my intention to make this address in any respect a political or controversial one, it is certainly a fact to be noted that an Englishman, presumably well acquainted with the facts, and speaking of England, and for England alone, in the columns of *The Times*, should employ the following expressions as regards the state of medical education a year or two before the passing of the Medical Act of 1858, and yet a year after my first introductory address to medical students in 1856:—

"Five-and-twenty years ago, except in the case of the small number of men who graduated in medicine at Oxford or Cambridge with a view to consulting practice as physicians, the education of a medical student commenced by an apprenticeship to a licentiate of the Apothecaries Company, which was then the chief source of the medical qualifications of general practitioners. The apprenticeship was rendered necessary by the Act of 1815, from which the Company derived its powers, and it usually commenced at about the age of fourteen years, so as to break prematurely into school education. The first year of the apprenticeship was often spent in the work of a surgery boy, varied by the preparation of medicines, and by the attainment of some knowledge of their properties. The later years were devoted to learning the business of conducting a medical practice, the art of talking to patients, and so forth; and, when the apprenticeship was concluded, a short term of hospital study formed a prelude to the single examination which, when passed successfully, permitted the candidate to work his will upon the sick under the protection of the law. Originally, the full term of five years' apprenticeship was served in the house of the master; but as the term

of hospital study² was gradually extended from one year to nearly three, the two demands were found to consume an inordinate amount of time, and the last two years of apprenticeship were commonly remitted, and were suffered to form part of the period of hospital study. Even then the total period of professional as distinguished from general education extended over about six years; and, as the examination might be passed at the age of twenty-one, was usually commenced not later than fifteen."

I interrupt the quotation at this point simply to say that one has to go back a long way in the history of medical education in Scotland to find a state of matters at all resembling the one here described. We had our errors and deficiencies, no doubt, and to some of them I shall allude more or less distinctly before I have done; but at no time within my recollection, nor, I think, within the recollection of those who preceded me, and whom I remember as my own instructors, was it even possible in Scotland to mistake a "surgery boy" of fourteen, prematurely withdrawn from school in order to manufacture pills and potions, and run errands, and make himself generally useful in a "shop" where he was under indentures to an "apothecary," for a regular student of medicine. To whatever extent the apprenticeship system held its ground in Scotland twenty-five or even fifty years ago (and far be it from me to say that in the hands of such men as Abercrombie, and others like him, it was not a system capable of much good), it was always controlled by a regular academic discipline, emanating mainly from the universities, but largely reinforced, I am bound to say, by the coordinate influence, and often rivalry, of some of the corporations in building up what is now called the medical curriculum. In Scotland, at the period here referred to, a medical student so-called, was rarely less than seventeen, or, at the very earliest, sixteen years of age; and he was bound at the very outset to constitute an *annus medicus*—i.e., to engage in an amount and kind of real study which effectually precluded the possibility of his being allowed to run wild as a "surgery boy," such as is alluded to in *The Times*' article; a type from which the Bob Sawyer, and Ben Allen of Dickens' well-known story was only a too natural outgrowth. I venture to claim for the Scotch medical student of twenty-five years ago, even while admitting many deficiencies in his education both general and professional, that he was (saving a few sad exceptions) for the most part not only bound over to learn, but really in earnest in learning, the scientific as well as the practical work of his profession; that he was not devoting days or years which should have been occupied by ordinary school training, to "the preparation of medicines, and the attainment" (by chance) "of some knowledge of their properties;" but that he was, as I hope and believe you are, seriously impressed with the need of really scientific training as a foundation, and actually carrying out such training in anatomy and chemistry, even during his first year. Moreover, it lies strictly within my personal experience in 1856, when I had already taught several classes of Practice of Medicine, some of them numbering more than 120, to declare that the type of medical student existing at that time in Scotland was one which it was quite easy and natural for me to address as an assembly, not of

undisciplined schoolboys out of school, but as "gentlemen" preparing, not without the solemnity and gravity proper to men, for the great business of life. I will add that this has been my uniform experience of medical students as a class from first to last; and I appeal to the words of both my introductory addresses in proof of the fact. I affirm that it would have been practically impossible to use the words of these two addresses, seriously and sincerely, to a body of men in whom the Bob Sawyer element formed any considerable intermixture; and I claim for our Scottish system of university and other regular medical education whatever credit may accrue to it from that fact.

I now return to the quotation from *The Times*; but what remains of it, though most important to us, is very short:—"The Medical Act of 1858 introduced changes by which apprenticeship was abolished and the hospital course extended to four years, so that up to the age of seventeen school education might be continued. In order that the opportunity thus given might not be neglected, the student was required to pass an examination in general knowledge before he was permitted to commence his hospital career, and two professional examinations were instituted in place of one. The general result of the change was to occasion a marked advance in the intellectual status of students and of young practitioners. They lost, it is true, the familiarity with the management of a practice which apprenticeship was calculated to afford, and they lost opportunities of seeing many common forms of disease which are hardly severe enough to enter hospitals, but they gain more than an equivalent for these losses in their better education and their greater self-respect. They gained an advance in intellectual training which rendered them better able than their predecessors to grapple with the complicated problems so often presented by disease."

It thus appears that the changes introduced by the Medical Act of 1858 into English medical education were in a great measure those which had been in operation in Scotland long before, under the influence of our three teaching universities, and the medical schools associated with them in Edinburgh, Glasgow, and Aberdeen. Not that I wish you to infer that our state was all that could be desired, or even all that, under more favorable conditions of medical legislation, it might have become. The Apothecaries Company, which I by no means wish to disparage, inasmuch as it has honorably striven to fill a position left to it by the other corporations, and thus to maintain the organization of the medical profession in England, long enjoyed a practical monopoly for its licentiates of most of the offices in that division of the kingdom which formed the usual introduction to general practice. The Royal College of Physicians during the same period long declined to admit, even as licentiates, any but the graduates of Oxford or Cambridge, thus aiming at a degree and kind of exclusiveness which effectually barred all possibility of its becoming the College of the medical profession. The Royal College of Surgeons, with a much more generally accessible, and therefore more popular, diploma, confined its whole attention to anatomy and surgery, under the theory that the other branches of a complete medical education were the province of the sister college, or of the apothecaries. Hence the anomaly of the "double qualification" which distinguishes England from almost every civilized country in Europe, for it involves the still more serious anomaly of the "single," or, as it may justly be called, the *half-qualification*, in virtue of which a man may enter into practice capable of performing operations, but entirely ignorant of medicines, and the diseases re-

² To a reader unaccustomed to the phraseology here employed, it may be necessary to explain that "hospital study" throughout this quotation corresponds to what in Scotland would be called regular medical study within the curriculum, whether in hospital or not. In the London schools, which are all attached to hospitals, this is well understood, but not so in Scotland.

quiring their use; or, *vice versâ*, capable of dispensing medicines, but almost entirely ignorant of anatomy and of surgical operations; and in either case far too much of a mere craftsman, far too little of an educated professional man.

The Scottish universities early perceived this anomaly, and long before the Medical Act of 1858 was passed, a regular curriculum of study had been instituted which was unquestionably (though still defective in many points) far more complete than anything hitherto attainable in Great Britain as a qualification for general practice. Not only so, but by a preliminary training in what we should now call the elementary biological sciences, botany, natural history, chemistry, comparative anatomy, and physiology, the mind of the student was opened to more than merely utilitarian views of his profession; the "surgery-boy" type, to which I have already alluded, was effectually eliminated, and replaced by a far higher kind of professional culture, founded upon a broad and generous estimate of the utmost that was then held possible between the ages of seventeen and twenty-one, to fit a man for the practice of every department of a profession which requires, and fully engages, all the energies of a well-disciplined intellect. It is true that in respect of what may be called scholastic training the Scottish graduates were often found deficient; the trifling modicum of Latin which in my time represented the whole of the non-professional culture required being a very poor substitute for the M.A. degree of Oxford and Cambridge, or any of the other insignia of the ideal academic man. True, also, that on the other side it was sometimes objected that the Scottish graduate in medicine was not sufficiently conversant with the details of compounding and dispensing powders and pills and mixtures, and, above all, draughts (at 2s. 6d. a piece) to be taken two, three, four, or five times a day; in other words, that he had not sufficiently mastered the technical details by which his neighbor, the English apothecary, was able to accomplish the great ideal of the developed "surgery-boy" type--the dispensing of immense quantities of "physic" in the most complicated prescriptions, to pass unquestioned down the willing throats of Her Majesty's lieges. But in spite of these two grave deficiencies, and perhaps many more in detail, of a mere real character than either of them, the Scottish University medical graduate has struggled on, with every precedent and every national prejudice against him, to a position of great credit and influence in the sister kingdom; and what is far better than that, to a more and more elevated conception of his art and the sciences on which it rests. The cause of this gradual elevation of his ideal is that the universities, which did not wait for the Medical Act of 1858 to make a beginning, were, nevertheless, fully prepared to advance with the times, and carry out as rapidly as possible all the improvements suggested by that Act and by the Medical Council which it created. A Royal Commission, appointed in 1858, in accordance with the Universities (Scotland) Act, enabled them greatly to improve their internal organization, just at the time when the Medical Act was initiating the revolution in English medical education and practice to which I have already referred. And now we are able to cite the very words of another Royal Commission, to show that our labors have not been in vain. "We readily acknowledge," write the Commissioners on the Medical Acts in 1882, "all that the Scottish Universities have done for medical teaching and examination, and we should hesitate to make any recommendation which, in our belief, would interfere with their usefulness or prosperity. We do not propose to interfere in any way with their

teaching, nor do we believe that students will cease to recognize the cheapness and excellence of their teaching." These, gentlemen, are not the words of Scotsmen, or of Scottish graduates, for on this Commission of eleven members there is only one Scottish M.A., who is also a professor in Oxford, and one Scottish medical professor, who is also M.B. of the University of London: the others being a peer, a bishop, an eminent English judge, a distinguished statesman, an equally distinguished naturalist, and others quite removed from the least suspicion of any but a dispassionate judgment upon the facts presented to them in evidence, so far as we or you are concerned.

The two addresses which I propose to reprint along with this one will, I trust, convey to you some idea of the direction and scope of these advances in medical education; not perhaps, by any distinct and separate statement of them, but by the glimpses they afford of the aspirations, hopes, and fears on your behalf of one who has been associated with medical students, almost without interruption, since he was a student himself; and this, not in the class-room alone, but in the hospital, and at the bedside of the sick, for nearly thirty years. This double relation to you as your teacher, continued over so long a period, may perhaps be considered to give the weight which comes from experience to suggestions in themselves not otherwise remarkable or profound; at all events you will, I have no doubt, receive them as tending to show how much the mind and heart of a university professor are put into his work, and how much the labor of teaching is for all of us lightened by the secure conviction that we possess your sympathy in all honest efforts to raise the work to a higher level. I am also glad to be able to tell you, and especially the juniors among you, that the testimony of all my colleagues goes to show that an increasingly high standard is being attained, gradually, almost from year to year, and that in particular the studies of the first year in anatomy, biology, and chemistry, show, to a very marked degree, increasing thoroughness. As I attach the greatest possible importance to these studies, not only in respect of their actual details of fact, but still more as a training of the mind into the paths of observation and reasoned experiment, which lie at the very root of all safe and sound medical education, let me press upon you the importance of continuous diligence and zeal at this the very commencement of your studies. Be assured that the labor of acquiring even what is commonly called *practical* information and skill in your profession will be greatly lightened, and your success greatly aided, by application to what is, and must ever be, the only foundation of a medical art that reaches beyond the merest empiricism. And now that all these departments may, according to the arrangements of this, and I believe all the other Scottish Universities, be studied in the laboratory as well as in the class-room, you may be assured that all the benefits which, in the first of these addresses, I ventured to anticipate for the development of practical methods of teaching, will be yours. It is, indeed, the increase of these methods in every department of our work that is mainly characteristic of these latter years of our Scottish University medical education. New buildings, new arrangements, new apparatus, new instruments of research, are everywhere found necessary, not only to convey the old truths, but to interrogate *nature* directly as to what is and what is not truth. And this *habit of mind*, which is nowadays not less than essential for success in every medical inquiry, can never be so easily and pleasantly acquired as in the first year of your studentship, in the fascinating

pursuit of biological research, whether in the animal or the vegetable kingdom. "Don't think, but try," said that mighty man of biological science, John Hunter; not that he meant to discourage thought or intellectual activity, for his own was of the most unresisting character; but that in his opinion all intellectual energy should resolve itself into active work, in the way of experiment and observation. This habit, so different from that of the mere literary student, finding his inspiration and materials alike in the knowledge that is got from books, must be acquired as completely as possible before you come to engage in clinical studies, for it is only to a limited extent that we can, in these, afford you the means of acquiring it. How are we to teach you effectually the fleeting phenomena of disease, if you have not for yourselves investigated the corresponding phenomena of health? How instruct you either in the one or the other to any purpose unless you have systematically cultivated your own faculties of observation and experiment by active personal research?

In the second of the introductory addresses to which I have referred I used these words in characterizing the existing state of the science and art of medicine:—"The art of medicine is at this moment in a peculiar position. The day of *orthodoxies* is over; the day of *real science* is only just dawning." It is worth while to return to these words for a moment, were it for no other reason than to inquire if the dawn has been at all brightening into day since they were written. The sixteen years since these words were written have been years of immense activity in research, and very much of what has been done in them tends, at least to fulfil the promise of a medical art of the future founded not on mere hypothesis, still less on dogmatic statements fortified by authority, but on accurate, continuous, and patient demonstrations of fact. In the first place, the art of diagnosis is constantly being improved by the introduction of new methods; and the basis of all these methods consist in this, that diseases hitherto quite obscure, or called only by conventional names corresponding to their most obvious symptoms, are being daily defined and rendered into much more exact conceptions in the light of an improved physiology and pathology, resting upon observation and experiment; so that what were formerly mere ancient names, surrounded by a halo of antiquity and traditional learning and skill, are now recognized symbols guiding the mind to well-understood lesions, as of the brain, spinal cord, heart, arteries, lungs, organs of special sense, and other well-defined points of the living economy, where, in many instances, the presence of the change, or lesion, can be actually demonstrated by such novel instruments as the sphygmograph and cardiograph, laryngoscope, ophthalmoscope, etc. I mention these newer instruments of precision, as they have been justly called, without prejudice to the much older and more established means which are now in the hands of every practitioner—the stethoscope, microscope, thermometer, and simple applications of chemical analysis—all of them employed in accordance with modern pathological investigations of a far more exact kind than any known to those great and wise men, from Hippocrates and Galen downwards to Hoffmann and Boerhave, from whom the art of medicine derives, or derived until the present century, the greater part of its current nomenclature of diseases. This great progress in the direction of realism in diagnosis is apparently quite boundless; for no one can tell, nay, no one can even conceive, how far the progress of a very accurate physiology and pathology, based upon physical

and experimental science, may lead us in the years to come; any more than anyone could in these latter years, by mere inspiration or study, have anticipated the splendid researches of Pasteur, the triumphs of antiseptic surgery, or the discovery of Koch's tubercle bacillus.

The mention of these splendid achievements, mainly of the last twenty years, and the last of them only of yesterday (as it were) recalls the fact that it is not only, perhaps not even chiefly, through the perfection of diagnosis, that the medicine of to-day is advancing from dawn into daylight. The enormous labors, the multiplied and varied observations and experiments, that have been bestowed upon these modern researches, in the genuine spirit of exact physical investigation, show that the progress even of diagnosis, and much more of the prevention and treatment of disease, is coming to depend to a greater extent than ever before upon that discipline of the mind which is to be found only among the consummate masters of physical science. Every day and every year removes us further from the period when it is possible merely to make chance hits in therapeutics, and so, by an individual happy thought, or particular prescription or nostrum, to compete with those who are investigating cautiously and experimentally the results of remedies in disease. The thorough investigation of remedies, in their action both on the healthy and diseased organization, is proceeding at a rate that seems, I confess, sometimes to be almost too rapid for security, but which has resulted, and no doubt will yet result, in achievements not less remarkable than the advances in diagnosis. And here let me give in my adhesion, in passing, to every word of the admirable address delivered the other day to the students of the Veterinary School by my colleague, Professor Cleland.³ Like him, I am not personally engaged in experiments on living animals, and have no reason to expect that I shall soon, or perhaps ever, be so engaged. But I hold it to be all the more on this account necessary to protest against a law under which neither the invaluable experiments of Pasteur on the bacillus of anthrax, nor those of Koch on tubercle, could legally have been performed in this country without repeated special applications to the Secretary of State, which might with great probability have been refused, or unreasonably delayed. Punish cruelty by all means, and repress it by restrictive enactments, provided you can devise such enactments as will strike impartially at the cruelties of science and of sport; but for a Parliament which tolerates, or even encourages the latter to single out men of science, some of them the most distinguished benefactors both of mankind and of the animal creation, and to place them under ban, forbidding them the freedom of action that is conceded to all other men until they are proved to have done amiss, is to my mind one of the most monstrous and inconsistent, if not hypocritical, positions that any Legislature could assume.

The rapid progress of sanitary and preventive medicine during the last twenty-five years is a subject on which I might well detain you, were it not that I feel that this address has already run to a length sufficient for its purpose. Nor is it necessary, nowadays, to draw special attention to this point. For the progress here has not been from dawn, but from almost absolute darkness into daylight. Every newspaper, every monthly magazine teems with the popularized results of sanitary investigation. He that runs may read. And nowhere less than in Glasgow are we likely to be allowed to forget the importance of this line of in-

³ Glasgow Medical Journal, November, 1882.

vestigation, or the many admirable results that have been brought to light by our excellent medical officer, Dr. Russell. The danger rather is, in my opinion, that feeling ourselves so well served, and at the same time so well represented in him, the medical profession at large will cease to interest itself in details which can be so easily handed over to a large and well-organized staff of public officers. This, I think, would be a great evil for us, not less than for the public. For preventive medicine, or the scientific study of the causes of disease with a view to their removal, is an integral part of the art of medicine in general, and cannot be withdrawn from the consideration of its professors without great injury to their function as healers. For these reasons, which I have always insisted upon in detail at every fitting opportunity in my own course of practice of medicine, I should be sorry to see the preventive medical service, or as it is called, the *sanitary* work of the medical profession, too completely specialized, and thus separated altogether from the rôle of private practitioner, as has been too much the tendency of late years. To you, as students, I would strongly recommend not to lose sight of either aspect of your future duties. Having acted as a public health officer for nearly ten years previous to 1872, I am able to speak from personal conviction of the valuable effect of such a career in educating the mind towards the recognition of some of the highest duties of the practitioners in the ordinary sense. And this education I shall hope to convey to you, in principle, even if I shall leave to others (as must need be) the development in your instruction of the daily increasing details which form the proper subject of a distinct sanitary course.

Gentlemen, I have done. All that remains for me is to wish you, on behalf of my colleagues and myself, a prosperous, animated, and a successful session. That will not be wanting, if you and we together approach our work in the right spirit. Be in earnest. Be diligent. Be modest and truthful. Help us, as we desire to help you, by mutual sympathy in our joint labors. Finally, *ora et labora*. Look for the blessing from on high. And if modern science seems, at times, to wean your minds away from God, look again, and look further and yet nearer, till in the reign of law you can perceive a truly divine order; in nature a living force behind nature; in the mystery of your own will the faint image of a higher will than your own, neither less nor more mysterious in its essence; in the endless descent of species, whether by evolution or otherwise, the infinitely multiplied reflection of a relationship to Him, who, while He is the Father of our spirits, and the framer of our bodies, is also "nigh to everyone of us," the Father of all the families of the earth, from everlasting to everlasting.

Inaugural Address

DELIVERED AT THE

GLASGOW INFIRMARY MEDICAL SCHOOL,

On November 1st, 1882.

By EBEN. WATSON, M.D., F.F.P.S. Glas.,

Surgeon and Lecturer on Clinical Surgery at the Infirmary.

MY LORD PROVOST AND GENTLEMEN—I consider it an honor to be asked to take part in the interesting proceedings of this day. I congratulate you all—teachers and students alike—on your taking possession of the admirable building in which we are now met as the future home of the Royal Infirmary

School of Medicine. I have in my time visited several such schools in this country and on the Continent, and I will say that I have not seen any one better, if so well, adapted to the purposes of medical teaching. The lecture-rooms are well lighted, well aired, and suitably seated to give all a good view of the lecturer's table, while the laboratories are convenient, and well fitted up with the necessary appliances for work. On the whole, I feel sure that if my friends the lecturers have not ample audiences to listen to their prelections, and if you students do not make good and satisfactory progress in your studies, it will not be the fault of the architectural arrangements for your comfort, or the educational requirements at your command.

Yours is comparatively a young school, and has much of its reputation still to make, and therefore I think it is a matter of no small congratulation to you that you have such a close connection with one of the oldest and best schools of medicine and surgery in the West of Scotland—I had almost said anywhere to be found—I mean the Royal Infirmary. You share its name, and to some extent its high prestige, and situated as your building is you almost seem to form part of it. Yet here, in passing, I cannot but express the hope that the day is far distant when the management of the infirmary will depart from that catholicity which has hitherto characterized it, and when that institution shall become in any degree less of a common platform on which the teachers and the students of all schools may meet on terms of perfect equality, and be dealt with in a spirit of thorough impartiality. I am sure I may take it for granted that none of you would wish for such a change. You are willing to stand, as a school, on your own merits, and one of the chief of these must ever be the advantage you are able to take of that older institution which has been doing such good service in the past.

I believe it is eighty-eight years since our infirmary first opened its wards for the reception of the sick and wounded poor, and it is pleasant to let one's imagination wander over that long period and lose itself in the attempt to estimate the amount of good it has done, not only to the immediate objects of the charity, but also through the medium of the many generations of physicians and surgeons who have owed to it their training and their skill. Then there is another aspect in which we may well be proud of our infirmary, for it has amply borne its part in contributing to the advancement of the healing art. Much in this respect has been done indirectly, as I may say, by those who after studying here have gone far away from our city, but much has also been done directly and immediately in the very wards of the infirmary. I feel that I cannot and ought not to enter here into details on this subject, yet I may be allowed to give two examples of what I have now said. There has lately departed from among us a veteran in surgery—Dr. Andrew Buchanan—whose ingenuity, guided and called forth by his experience in our infirmary, has afforded us several new procedures, and especially one great operation which will make his name long remembered with esteem. Then you doubtless know that it was in the wards of the Royal Infirmary that Mr. Lister was first led to make that application of Pasteur's discovery to the healing of wounds which has resulted in the antiseptic system of surgery—a system which has revolutionized the art, and now enables us to perform with safety operations at which the boldest surgeons of former times would have stood aghast.

Now I have thus, in few words, brought before you the high and established reputation of the Glasgow Royal Infirmary as a field of medical and

surgical training, not to boast of it, but for the purpose of urging upon you that your best policy is to make your character as a school mainly rest on its practical nature. Surely this is to be expected of a hospital school, and I think it will best recommend you to all concerned, to the authorities who legislate on medical education, as well as to the students who may fill your halls.

Some time ago medical education in this country, especially in England, was too practical. The young aspirant to our profession was sent as an apprentice to some general practitioner, and he was taught to make pills and potions, and by-and-by to visit patients, and only after this course of instruction was he sent to school or college to pick up what science he could. After that period came a reaction, and then the only desideratum appeared to be science, and not practice. It was to be taught by specialists, and studied without reference to its application. Natural history, botany, and chemistry, even anatomy and physiology, were to be studied by the perplexed and overburdened student as pure sciences for their own sakes. The idea of medical chemistry, of surgical anatomy, or of physiology, as the institutes of medicine, was scouted as far beneath the requirements of the day. But somehow it has been discovered that there is a mistake in all this; that such an education might make scientists, but would never make practitioners of medicine; and hence another reaction is, I think, now taking place, and I hope it will not be carried too far, in favor of more practice for our students, even if they learn less science. In proof of this you find *THE LANCET*, which is a very good index of opinion in our profession, enunciating the dictum that medical students of the present day are "under-educated and over-examined."

For my part, I would rather say that they are often not well—not quite rightly—educated. They are over-educated, if you like, in some things and much under-educated in other things. Take physiology, for example, with the teaching of which I am very familiar. Is it not the fact that the time and the energies of the student are often wasted on what to him are trifles, while the great and important truths which are to regulate his practice are slurred over in so superficial a way that he is apt to lose sight of them altogether, and really not to know much about them? Some years ago I visited the physiological laboratory of a distinguished university at a considerable distance from Glasgow, and it so happened that some students were sitting at the table when I was shown round by their professor. He explained to me that they were answering the written questions for one of their degree examinations; and what do you think was the nature of the questions over which the perplexed students were cudgelling their brains? Were they about the functions of the kidney, or the liver, or the lungs, or any other important organ of the body? No. The students were required to describe certain very pretty physiological instruments, fine balances, sphygmographs, recording drums, etc., which were all placed before them on the table under their appropriate glass cases. I hope that did not form the whole of their examination in physiology; but the fact of this being such a remarkable part of it showed that in the lecture-room far too much importance had been put upon the methods of physiological investigations, while the results, the facts of physiology as applicable to practice, must have been proportionately less insisted on and drilled into the students' minds. The same thing might likewise be said of what are called the practical branches of the curriculum, though in my opinion all your studies ought to be practical from ana-

tomy onwards. Suppose surgery, for example, to be taught apart from actual practice on living men and women, and anyone can see how useless it would be. The fine-spun theories of the lecturer may be plausible enough as he puts them, and the cases which he relates of course all turn out successfully, but one grain of demonstration in the wards of a hospital on the living subject must be acknowledged to be worth bushels of such oratory. The conclusion, then, to which we are necessarily driven is that lectures may be and ought to be the best preparatives, but are only preparatives, for work in the wards of the hospital; and I augur well for this school inasmuch as I hope and believe that the sentiments I have now expressed accord pretty nearly with those of your teachers, and that they will endeavor as soon and as constantly as they can to refer you to what they will excuse me for calling the best part of their teaching—viz., that which they show you in the infirmary.

With the other part of *THE LANCET*'s dictum we have not so much to do here; but I have no objection to state it as my opinion that students are over-examined, because too much is required of them at that early stage of their history, and because their examiners are too often specialists in their branch who are apt to forget how defective was their own early knowledge, and also how little they know of the other subjects, on all of which the student is expected to be well informed. Surely too much is required of our students, regarded *en masse*. The bulk of them are destined to be general practitioners, and not operating surgeons or consulting physicians, and I think that the true remedy for much of the complaint now made, both of over-examining and with still better reason of unequal and uncertain examining, lies in the institution of a single board of experienced examiners, not being teachers, for each country, and a minimum qualification essential for all, but not essentially the only one for all. I say, let there be one qualification sufficient, but not more than sufficient, for a license to practice, and let those who can and wish it add to that qualification other and higher qualifications, according to their circumstances and prospects in after-life.

But, as I must now draw these necessarily brief remarks to a conclusion, I wish, for the few minutes longer of your time which I can occupy, to urge still more specially upon you students to take fuller advantage than some of you do of the great hospital which is so near you now. Afterwards you may enjoy no such opportunities, and in your possibly distinct practices you may often long in vain for another look into the wards to see how this or that case is managed there. My advice to you in plain words is, that you should seek for dresserships early in your career, so that you may have the right and be almost forced to come into actual contact with the patients. The more and the earlier you work with them the better will you be fitted for your future duties. You may not fully understand all that is said or done in the wards at first, but taken along with the instructions you receive in your classes, it is strange how quickly the required knowledge will come to you if you put your heart into your work. "Nulla dies sine linea" is a good old maxim, which in your case may be taken to mean, Let no day pass without its lesson learnt, its fact stored up in your memory. Then by the end of your sojourn here your minds will be filled with practical knowledge, and your heads and hands accustomed to bring that knowledge to bear on your patient's circumstances.

To stimulate your zeal I would remind you that the character and success of this school depend

greatly on you. Your character and behaviour now will be regarded, and rightly regarded, as the index of the character which your school ought to bear; while your success hereafter will be its best recommendation to others. In short, I wish to more than hint at a qualification not often spoken of by lecturers, but which is almost as necessary for success in practice as a good knowledge of your profession—I mean quiet and gentlemanly manners, and a something in your style indicating kindly interest in all who consult you.

If you enter the graveyard of our cathedral and turn a little to the right you will come to the tombstone of Dr. Peter Low, the distinguished founder of the Faculty of Physicians and Surgeons of this city, and you will read in his quaint epitaph some such words as these—

“Though his physic sometimes failed,
His pleasant humour aye prevailed.”

I wish we could all have such a pleasant humor. Try to have it as yours from the first, and then your recollections of this happy student-time which you are now enjoying will be unclouded with regret; and in your future lives, if cares must come, they will be less bitterly felt by you because they will be shared, in sympathy, by others whom you have assisted and comforted in their troubles.

Considerations

BEARING ON

OUR PRESENT KNOWLEDGE OF FEVER.

A First Lecture.

By WALTER MOXON, M.D., F.R.C.P.,

Physician to, and Lecturer on the Principles and Practice of Medicine at, Guy's Hospital.

GENTLEMEN—In pursuance to the usual course, I have now, by what is rather an abrupt change, to turn your attention to the subject of Fevers. I conceive that a lecturer professing to teach the principles and practice of medicine must, when his subject is fever, proceed to explain to the class what fever is from the point of view first of principles, then of practice. Speaking now very generally, I suppose that principles must here mean a consideration of what fever is in itself, and practice must mean what you will do with fever when you meet it.

Taking the principles first, our question becomes, What is a fever? Well, then, what is a fever? As I do not know sufficiently well to say offhand, I thought it best to look in a book, and I chose what I regard as the best recent work on medicine. In it I find the esteemed and accomplished author saying, “By the term fever is meant that abstract condition which is common to all so-called febrile disorders, and the presence of which gives them claim to that designation.” Now I am always a little timid when dealing with anything that deliberately calls itself abstract, and I am ready to confess to you that I feel myself very insecure in abstract questions. There is an un-English lucidity—I might almost say an alien pellucidity—about them which estranges them from one's practical middle-class mind; so that, indeed, it is necessary for me to form a habit of familiarizing abstractions to that mind by clothing them in some concrete form, or at least by paralleling any puzzling ones with others better known to me. Let us do so in this case, and instead of fever suppose we put *heat*. We shall then perhaps get an idea as to how far our inquiry “What is fever?”

is advanced by the definition I have quoted to you. Let us ask, What is heat? and answer in parallel terms: “By the term heat is meant that abstract condition which is common to all hot things, and the presence of which gives them claim to that designation.” But really when I look at this definition I am afraid your physical philosophy will not be much enriched by such a piece of information.

Well, but what in its own nature is a fever? Be patient with me. Half the answer is often obtained, and the other half commanded, by asking the question rightly. Again, then, let us try the compass of the question as we just now tried the value of an answer by paralleling it in a better-known field of inquiry. Suppose we ask, What in its own nature is a horse? Now, you would not say, “By the term horse is meant the abstract condition common to all equine animals, and the presence of which gives them claim to that designation,” for you will see that that really involves a fallacy. As other animals than the horse are equine, just as we shall presently see that other diseases than fever are febrile. Well, from the point of view of such unlimitedly general principles as would touch the nature of the things dealt with, What is the nature of a horse or of a fever? I must answer you that, in truth, we do not know the nature of anything in itself; we do not know the nature of our own bodies, nor even the nature of our own minds. In fact, we do not know what nature is. It is a growing, and we no more know how it comes about than our bones grow than the old ecclesiast did. Our language cannot fit itself to the processes and results of nature or growing. All we do is not nature, but fabric. And our readings of nature are in language of fabric; even when they are not unconscious fabrications. The laws, or, as Bacon termed them, “forms” of unliving things, are perfectly expressed by the language of science, which follows their *a posteriori* progression with measure and rule. But the laws or forms of living things are not *a posteriori* causes, but *a priori* reasons for existence. So that, if I may so speak, dead nature exists *a posteriori*, but living nature *a priori*. And human language must in some sort be read backwards if we are to catch the meaning of the life of living things. The genius of Darwin has left us a formula which works somewhat like the integral calculus works, so that by its means reasoning belonging to straight line *a posteriori* nature is turned at an infinitude of little tangents, and so fitted to the immeasurable, unknowable curved lines of the forms of *a priori* living nature. But we must beware, lest with the aid of this powerful theory of natural selection we find ourselves contentedly reasoning in circles. This is not one of my easy ideas, and lest it should be too pellucid I will proceed to clothe it in a concrete form, and ask you to observe how, even in your simplest readings of nature, even in the description of the simplest anatomical facts the discrepancy between the nature process and the mental process at once appears in its primitive simplicity. Thus you say the biceps muscle arises from the scapula and is inserted into the radius; but, in fact, the biceps muscle grows in its place, and grows in continuity with the scapula and radius, and it never arose from the one or stood in a past participle relation of the verb to insert as regards the other. You cannot conceive how it really comes about that the continuity of bone and tendon and muscle grows into being, and when you proceed to state a history of it you can only do so in such terms as your mind and its language are capable of, and so you speak as if the growing of it were much the same thing as your making of it would be, and talk as if you, or somebody like you, had made first a scapula

and then sprung a biceps from it, and afterwards fastened it on to the radius.

Thus, it is true that in dealing with living nature our language tends to put us mentally athwart the facts of the case, even as concerns things that you can realize and handle, like the biceps muscle. But inasmuch as what we have to know of and to do with the biceps is comparatively simple, we are not led into any practical inconveniences, for the biceps, capable of that measurement which constitutes science, is there before your eyes, to keep you steady and prevent your imagination from playing its tricks. But our question is of the nature of a fever. And we find our last new book on medicine defining fever as an abstract condition which gives claim to a designation; and you will at once see that a thing of that kind is not so easily got hold of as the biceps. And I am saying all this so that we may understand each other as to the proper character and the limits of our inquiry; and not carry it too far, lest we should feel dissatisfied because we cannot know of fever what we do not know of the biceps, and that we may not lose ourselves in wandering after questions as to the nature of fever, such as could not be answered regarding the most tangible and ponderable living objects.

We begin, then, if you please, with the clear knowledge that we cannot know the nature of fever, and so we will not ask it. We must, then, resign so much of what we, in the most general view, may seem to profess in the term principles of medicine.

But it is now time that we take up a more positive position and endeavor to learn what the principles of medicine in relation to fever really are. Yet it may be well to quite clear up this word "principle," lest it should contain anything vague and pretensions. The word "principle" is very ambiguous in its signification; you find it in the sphere of morals with the most noble absoluteness of meaning in the whole range of language—as when you say "a man of principle." And there are sciences in which the principles are abstract and absolute, as in the case of mathematics. And thus the term "principle" assumes to us, since we all have been taught morals and have learnt mathematics, an absoluteness coming from our prior experience of its use; so that the word "principle" claims to express an absolute masterfulness of obligation. And in expounding the principles of medicine with regard to fever, we naturally look for some general principles about fever whose obligation is absolute, and masterful, and commanding. But in truth, it must be confessed that when we come to deal with the facts of living nature, we are obliged to let go the commanding style in any application of the word "principle." In short, we have to seek for our principles patiently and laboriously amongst the facts of the cases. And, indeed, we have to find our principles amongst the facts, and we have to be content with the most commonly and generally recognizable facts and consider them our principles. Thus in physical science, and especially in the physical science of living things, the greater and more absolute facts. For in dealing with real things, and especially in interfering with the health, even if it be the grossly bad health of other persons, we must have a direct grasp of our principles, and this I have shown you to be the same thing as to have a direct knowledge of the general facts, so that what we say may be as little as possible second-hand, for to get in the habit of speaking or acting at second hand is to lose the power of meaning, and the value of a doctor varies according to what he can himself mean to do, and do. And when you say a thing at second-hand you do not

quite mean it. Of course, when you say a thing is, you mean that it is. But if you have not seen that it is, your meaning that "it is" is necessarily less directly grounded. And, in fact, if you say a thing is, and mean it all you can from hearsay knowledge, your "is" comes—as the hearsay is more distant—to be really worth no more than its value as a copula in an abstract proposition, such as the "is" in the statement that "a griffin is a dragon with wings." The value of the copula varies as the directness of the utterer's knowledge. You can only mean when you know and believe, and from this digression I wish to lead you back with a firmer grasp of the greatest truth a young medical mind can inform itself upon. The great truth, that inasmuch as your future is of value to others in proportion as you can mean to do and mean to say, and inasmuch as you can have no proper meaning from indirect knowledge, you must know the principles or general facts of your art at first hand and for yourself.

Our question has now transformed into, What are the general facts common to the several kinds of fevers? Now, I am really afraid that you will accuse me of deliberately drawing you aside into obscure questions whenever we approach a clear one; but though I am speaking to very various minds, various in capacity and tendency, some of which will think I am talking nonsense, and others will think that there is much more of profundity and importance than there really is in it all, yet I must follow my own judgment of what is needful, and ask you now to consider, in an abstract way, What do you mean by a kind of fever? This word kind is so constantly employed by every one of us with variations in its import, that it is worth our while to clearly understand in what sense we may rightly use the word "kind" when speaking of a kind of fever, as compared, say, with the sense in which we use it when speaking of a kind of inflammation. It is well not to use this important word vaguely. Shall I tell you a little anecdote to impress one of its possibly clear significations on your memory? The anecdote involves, I regret to say, a confession; but it was in the days when I was young, and not under proper self-control. I chanced to be placed, for the purpose of tuition, with a gentleman of an entomological turn of taste. The delight of this gentleman in discovering a new fly inspired my always sympathetic nature with the wish to afford him such a gratification. But new kinds of flies could not always be found, especially flies new to him, so one very hot afternoon it struck me to give him his favorite pleasure by a somewhat indirect and factitious proceeding. Inspired with this purpose, I caught a large housefly and rolled it carefully in the carmine powder and set it free, taking care that it was well within sight of my instructor. The fly was seen, and I do not think I ever witnessed such eagerness of pursuit. The day, as I said, was hot, and the fly was lively, so that my instructor, and I at second-hand, had good sport. When the insect was at length captured, I may tell you at once that, after handling the insect for a moment, my master concluded that it was not a distinct kind of fly; yet in the mere matter of color it had as much ostensible claim to be considered a new kind as digitalis purpurea to be considered a distinct kind from digitalis alba. But the reason why he never thought of allowing the red fly to be a distinct kind was that he at once understood when he touched it how the fly came to be red, and, I am sorry to say, shrewdly guessed who made it so. Now if, instead of finding red powder on the fly, he had caught such a fly red in a manner he could not explain, he would have pinned it out on cork, and have called it "*musca rubra*," or

something equivalent. What I want you to perceive is, that a usual and a true ground of distinction of kind is the existence of differences which you are unable to explain; and perhaps, indeed, that would be the only general philosophical ground for distinction of kind, were it not that with reference to living things another system of facts affords narrower and more special and proper grounds of distinction of kind. I mean in the power which living things have of reproducing their kind which power of reproduction is the basis of zoological and botanical distinctions of kind. But even amongst cattle breeders who are most concerned in this question, the idea of kind belongs rather to resemblance than descent, as you may note from their speaking of a casually varying individual of a flock or herd as being out of kind.

Now, with reference to fevers, I wish to draw your attention to the fact that we are able to be clear upon the idea of kind, both in the wider and the more restricted sense which I have just laid before you; and that in this relation of kind fevers differ from all other classes of diseases; at least this is true of the contagious fevers, in which the disorder is propagated in a manner only comparable to descent by generation. Indeed, one of the most practical of the fruits of wisdom which experience will develop in you when you have seen much of professional work amongst families will be the readier conclusion of the nature of an attack of illness by tracing the kind of fever to which a child has been exposed. And, again, it may be said that the chief evidence of the distinctness of kind among some of these contagious fevers has been obtained through most patient investigation and watching of local epidemic attacks of one fever or the other, by which it has been proved that each disease spreads in its own kind, and not in any other. This is the only conclusive argument to prove that typhus fever is distinct from typhoid fever; for all the differences which I shall have to detail to you as characterizing typhus in its diverg-

become dogs, nor dogs to become cats; so typhus never varies to become typhoid, nor typhoid to become typhus. This certainty of kind in fevers marks a vast difference in their nature and relations as compared with those diseases which I shall have to introduce before you when speaking of disorders of the lungs, heart, and brain. I shall then detail to you the characters of many things spoken of as kinds of diseases; but the word kind is much looser here, and indeed has only a quite vague and popular application. I remember being amused by a passage in some story. The author had got one of his characters into a hospital, and made a little poor fun in setting out the effect on the ignorant patients of the learned doctor's clinical remarks to his group of students. The impressions of the patient were rendered something in this way, "The doctor said as how the thing what No. 3 has got in his head is the same as No. 6 has got in his stomach."

I suppose that the clinical teacher must have been asserting in the hearing of the author of this character that inflammation of the brain was of the same kind as inflammation of the peritoneum, and if the question was raised, Is meningitis the same thing as peritonitis? you would certainly see that meningitis differs from peritonitis, not like typhus and typhoid differ as generated kinds differ from each other, but meningitis and peritonitis would be always held to differ by differences untraceable in their nature, as the purple and white foxglove differ, so long as you consider them to be separated by the inalienable peculiarities of origin and relationship which separate the meninges from the peritoneal sac. But if you think that the physiologist and the pathologist could really set forth and explain all the differences between these membranes, then would peritonitis and meningitis differ in kind to you only when you used the word kind in a vague popular way, as when one might say that a knife is a different kind of a thing from scissors, or a pen from ink, in which case the phrase "different kind" means no more than that

PYREXIA OR FEVER.

PRIMARY.				SECONDARY.	
CONTAGIOUS.		NON-CONTAGIOUS.		CONTAGIOUS:	NON-CONTAGIOUS:
ERUPTIVE.	NOT ERUPTIVE.	Miasmatic:	Autogenetic:	Epidemic wound fevers. Erysipelas.	Pneumonia and other inflam- matory fevers.
<i>Continued:</i> Typhus. Typhoid. Relapsing.	<i>Brief:</i> Small-pox. Measles. Scarlet fever. Rötheln. Roseola.	Whooping-cough. Influenza. Erysipelas.	Intermittent. Remittent. Rheumatic. Gouty. Erythema nodosum.		

ence from typhoid might be differences through accidents. I have seen a very crowded outburst of typhoid eruption amongst the rash in typhus, and *vice versa*. Ulcerated intestine might be a character superadded to some cases of typhus, as pneumonia is superadded to some cases of measles, or as diphtheritic disease of the fauces is fatally superadded to some cases of scarlatina. But when you find typhoid always breed typhoid, and typhus always breed typhus, then all question as to distinctness of kind ceases, or at least lapses into the more general question, whether species of fever can be constant when, as modern biology has shown or brought up to a general belief amongst all biologists, no species of any living thing either is constant or ever has been constant. Not that this last reflection brings existing species nearer each other; for though they vary they do not vary towards each other, but always away from each other. They ever diverge; cats never varying to

the differences are untraceable as regards the intents and purposes before you at the time. In short, popularly the word "kind" is applied to things in virtue of any likeness sufficient for the purposes of the occasion. This digression has been so long and our progress in the direct line so short, that you may scarcely remember that we digressed from the question, What are the general facts common to the several kinds of fever? into the question, What do you mean by a kind of fever? And now we must go back to the original question, and I must proceed to show you what those general facts are which are common to all fevers.

Stay though, we must have another digression, for I am afraid you might be content to regard every distinct kind of fever merely as a distinct sort of fever, and thus to ignore the relations of the several kinds of fever to one another. But if you take the facts of the several kinds of fever you

will find that there are some of these facts special to each distinct kind, and others that are general to several of the kinds. And on perceiving and admitting this you must perforce regard the group of kinds of fever which have general facts amongst them, which facts are common to all of the group, but absent from all other kinds not included in the group. I say you must regard the group of kinds which have the common characters as in some sort genera of fever. And when you further find that some of the groups of kinds have facts common to such groups but absent from other groups, the groups thus connected must associate themselves into yet more general groups which become orders. So that, for example, Mr. Jones's fever has characters which bring it together with all cases of scarlatina, but amongst those scarlatinal characters is the fact of shorter duration, which makes scarlatina differ from continued fevers, but agree with a group including measles and small-pox, etc. But, again, amongst the characters common to all the group so included are some characters, such as the possession of a specific eruption, which bring Mr. Jones's scarlatina into association with the more continued fevers, typhus, typhoid, etc., but which separate it from all non-eruptive fevers. Mr. Jones thus becomes a case of the species scarlatina of the genus not continued of the order eruptive of the class contagious fevers, and thus you, as it were, perceive whereabouts Mr. Jones hangs upon the family tree of fevers, and you view his position with a greater total comprehension. Such a family tree view is a nosological view of fevers. You can construct such a tree as to the family of fevers, but not as to other diseases. The nosology of other diseases is only an appendix of the anatomical and physiological arrangement of the several organs and parts of the body.

You will, I daresay, remember that all the while our question is, What are the general facts common to the several kinds of fevers? Well, now, you can see that we have reached a point from which we are at an advantage in solving that question. For when we have recognized what are the general facts that form the bonds of association of the several generations and families of fevers, then, as we have seen that these facts are themselves the principles of medicine with regard to fevers, we find that we thus reach at once our general principles, and can study them with due observance of their order of succession in importance. The facts common to the most inclusive group will be the most general facts and principles, and so on with less general facts to the less inclusive groups. Now, if you look at this scheme of fever, you observe that the most general division of fever is into primary and secondary fever. This is, indeed, not only the first in the order of nosology, but the first in practical application. In every case of fever that comes before you the first question is, Is it primary or secondary fever? One question only can precede this—namely, Is it a fever at all? What is fever? In its most general sense fever is still febris, fervid heat, and its only and sufficient criterion is heat. Not the feeling of heat. A patient may feel hot to you or to himself when he is really not so, and may be shivering with cold when he is thermometrically very hot, as in the cold stage of ague. But since the introduction of the clinical thermometer you can easily be quite sure of fever, or, as in this widest and most general sense it is more properly termed, pyrexia. You decide it by the thermometer. If his temperature is above 100° the patient has pyrexia. But in a vast proportion of cases pyrexia or feverishness is secondary to inflammation; and, in fact, before you pronounce a case to be fever you must be sure there is no local cause

on which the pyrexia depends. Search for local inflammation. If there is no local inflammation, then it is fever, and it is called primary, or essential fever, or "fever" as distinguished from mere pyrexia. The next great characteristic, in which you find the first line of division of essential fevers is the character of contagiousness. This, too, is not merely first in order of generality, but in order of practical importance. When you are sure that the case is some kind of essential fever you will be asked by the friends, Is it contagious? A very serious consideration, on which depends the taking of immediate steps to ensure the safety of those around, steps which are annoying, troublesome, and costly, and which therefore must not heedlessly be enforced, but which are so imperative when necessary that there is no forgiveness if you fail to take them in due time.

And here I think it will be well to consider in a general way, and once for all, the great fact of contagion which is common to the more dreaded and deadly of the fevers. What do we know about contagion? Well, we seem on the very brink of knowing all about it, and yet we must perhaps on that very account be cautious. It is well to be circumspect on brinks. And the attitude of science is properly one of caution, especially of caution against the very probable. Science used to be always being misled by the probable. Therefore now let us challenge strictly all evidence when a general conclusion is to be drawn. The general conclusion is none other than that all contagious fevers arise through the entrance into the system of what are called "germs," and that these germs are of the nature of living organisms, such as have from the first microscopical ages been known to microscopists as bacteria spirillum, micrococcus, etc. Many an hour have I spent in watching these, but never thought of associating them or any of their kind with fever; yet what I witnessed many years ago might have awoke a quicker perception to the anticipation of recent discoveries. I was watching floscularia, a stationary species of rotifer, resembling a relatively large bell with a Japanese quaintness of design about its figure. These creatures had come in large numbers in the aquarium at my dining-room window. Their textures are entirely transparent, and I was discovering their sense organs and the ganglion that represents their brain, and in particular I was watching the curious disappearance of a pair of bright-red eyes, which these creatures possess whilst they are young and active—eyes which, like some other creatures, they lose when they grow old and acquire established positions. But, to my great sorrow, my floscularias, which had been thriving and multiplying freely, began to die away before I could finish all the observations I had hoped to include in a paper which is in the Linnæan Society Transactions. As the creatures sickened they became turbid instead of clear; and whilst I was endeavoring to follow the nerves from the ganglia I saw that the obscurity which clouded them was due to the presence of countless bacteria, exactly such as I am now familiar with in Koch's figures. I now know that I was witnessing an epidemic of bacterium fever in a population of floscularias, but I was not seer enough to see what was before me then, as I looked for and thought only of nerves.

In 1873, Oberheimer, of Berlin, discovered spirillum in the blood of persons suffering from relapsing fever; and the fact that such organisms are in the blood in relapsing fever is beyond all question. This discovery might at first seem only a further extension of the knowledge we have of scabies through the finding of the itch insect. But there is this vital difference, that whilst the itch

insect is living his quiet little life as an unwell-come guest, he creates no general disturbance except for some importunate sensations; whereas when spirillum gets into the system there is fever, and indeed intense fever. Evidently, then, the spirillum has a much more intimate and general relation with the system than the itch insect has, and it becomes a most interesting question what those relations really are. The facts are simple enough; indeed, are they not precisely such as science has long been aware of as occurring in the popularly well-known processes of vinous and acetous fermentation? In the fermentation and in the fever have we not definite systems of turbulent changes determined by the presence of living germs? Even before the discovery of the yeast plant fever was seen to resemble fermentation. Well, there we have a familiar and apparently close analogy to incline us to the view that relapsing fever, at least, is a colonization by foreign living creatures which in some way breed a poison, or which, as some think, fill up and choke the life out of vital parts of the frame. This is a simple and plain view, and is easily accepted and understood. But the truth may not be so simple and plain, and I wish to draw your attention to an alternative view. This alternative view will appear to you if we ask the question, Are these spirilla—which, by the way, much resemble some spermatozooids—spermatic in any sense useful to recognize? Are they the offspring of the human body endowed with powers to disturb the vital processes of other human bodies? In a general way, there is a range wherein life and fever show enough in common to have been more than merely poetically or metaphorically parallel. For fever is like life in having its times of duration limited though uncertain, and in having its stages so that you can anticipate them, and you can recognize whether the fever is a young or an old fever; and, as our very question shows, fevers reproduce their kind. Here, then, are all the characters of a life: its uncertain yet sure limits; its stages of development; its power of reproducing itself. And so a fever might appear to be another life lived in and by its sufferer, and the human fevers would thus become as it were, episodic lives supplementing human life; so that you have not quite lived until you have had your fevers; though it may be found for you that you have quite lived when in the middle of one of them.

There may be too much of some sorts of life. In strychnia poisoning or in laryngismus stridulus, for instance, the convulsions themselves cause death. But convulsion is itself an act of life, and so you may die by too much life. Life is a paradox, look at it as you will. You know that from the chemist's point of view life ought to settle itself at once by the several elements obtaining their favorite affinities, and being forthwith satisfied, which they never do until life is over. Life is such a paradox. But from my present point of view life itself is, as it were, a protracted infection of the germ by the sperm, and the living body remains during its life germinal to other infections when suitable spermatic elements come in contact. If this view seems to you more fanciful and supported by less analogy than the fermentation theory, I will at once put before you what is a serious difficulty in accepting the fermentation theory of fever. On this theory it is not very difficult to explain how it comes to pass that one attack of a contagious fever protects from the danger of that fever ever after? This, as we shall subsequently see, is not strictly true, but it is generally true. If fever is merely colonization with germs who feed upon and live in the body, why should they not come and feed and live again? The only

explanation I remember to have seen offered is that the unsophisticated human frame is born with a small amount of some very special food of which the fever germs are very fond, and it is supposed that these little organisms are so fastidious, that they will not take any other nourishment, so that when they have consumed the whole supply of this kind of food, they die or depart to other feeding-grounds. Now, seeing that according to biological science these germs are only protoplasm, it would be very surprising if it turned out to be true that minute unspecialized organisms such as swarm in every puddle where organic decay is progressing should refuse to accept any nutriment other than some inborn kind of delicacy; and when you reflect that there must be a number of these delicacies, for no fever germs will pasture on the food of others, and in fact the ambrosia of one is caviare to the rest, it puts no little strain on the highest genius for imaginative scientific belief to suppose that we are all sent into the world each to bear a little special supply for the several kinds of fever germs to thrive upon.

On what seemed to you perhaps the more fanciful view we may suppose that the human frame can cast off spermatic elements which when they enter other human frames engage in an activity remotely like that which originates germination, so that for awhile, if I may so speak, the protracted germination which constitutes life is itself reinfected and diverted. We may suppose that this activity constitutes the fever; and that when once the fever is over and its life lived, it does not return. Were this really the case, would you not expect that these episodic lives would be most probably lived during the actively growing germinal years of earlier existence, or, in other words, would not the fevers attack children? Which indeed they do. Again, if you suppose the immunity from subsequent attacks which fever affords to be due to exhaustion of materials suitable to the parasitic germs, how can you explain those rather frequent cases in which typhoid fever or measles repeats its attack upon the convalescent patient, and even recurs a third time after defervescence? For if you suppose the immunity to be due to exhaustion of a material suitable to the parasitic germs, how can you explain the reappearance of the fever, and therefore of the germs with their supplies, just after the cessation of the first typhoid attack has shown that all supplies were exhausted? But if you concede that this proves the immunity in question not to be due to such exhaustion of supply, then how do you at all explain that subsequent immunity which is so marked and so happy a feature in the history of contagious diseases?

Well, then, the recurrence of typhoid fever cannot be a question of food of the germs. And if not, we must suppose that the repetition which makes three typhoids is due to some measure of time in the life of the typhoid germs themselves, so that each brood lives just the time of one attack, and the next attack is due to other broods whose life has a time limit equal to that of the fever. But these germs are minute unspecialized particles, which reach their little perfection with extreme rapidity, and all that is known of their rate of growth is the reverse of conformable to periods of fever measured by weeks.

On the other hand, if we suppose the fever process to be an episodic vital action between the elements of texture of different individuals, there is nothing contradictory in supposing such vital actions to be sometimes lived through a second or even a third time. Not long ago at the Pathological Society, there was under debate a question how we should explain the late manifestations of

so-called tertiary syphilis and the syphilization of the foetus whose mothers, having passed through the disorder, are not then actively diseased. And I endeavored to show that these and similar facts are explicable by assuming that tissue of recent origin, or tissue by chance left unsyphilized during the syphilitic fever, undergoes impregnation with the syphilis germs which chance to come from habituated older parts of the frame into contact with the new tissue, either through such an intercommunication of the several parts of the frame as is supposed in Darwin's theory of paragenesis, or, else, in the more easily understood instance of the syphilitic foetus, through the blood of the mother. And I pointed out that the observations of Mr. Tomes on the Haversian spaces of bones, proving that fresh texture arises and replaces old texture in the life of adult bones; that these observations make it probable that similar new formation occurs in other textures, giving rise to new-formed tissue, which would be germinal to or capable of vitally receiving any poison which might be transmitted to it from the already syphilized general textures. If this is true, though I now cannot give you all the evidence in favor of such a view, then, in tertiary syphilis we have occurring within the body of one and the same individual an infection of young and virgin tissue by the poisonous offshoots of older tissues charged with a cause of infection to which those older tissues are themselves no longer susceptible. Such a fact would form a step towards the admission of a like infection by the tissues of an habituated individual of the tissues of another not yet habituated.

But I have hitherto overlooked a branch of evidence of the existence of which you must be duly apprised. Though I may be allowed to deal judicially with the facts as offered, and facts are offered by the most accredited observers which would go to prove that the germs of a fever to which mice are subject can be grown into a fungus which produces spores, and that the spores of this fungus will reproduce the fever in other mice, whilst the fungus threads fail to do so unless spores be present. Such researches are, of course, very elaborate, and when admiring the thoroughness and continuity of the work, and the skill and foresight displayed in the views of the experimenters, we must recognize also the extreme difficulties in avoiding fallacy, and the corresponding possibility that fallacy was not avoided; for to obtain the germs of fever about the 10,000th or 20,000th of an inch large, and to plant them and grow them to a fungus, you must be able to follow their individuality; nay, you should never, if possible, lose sight of the individuals. It would be well to identify these germs; and, indeed, it would be much more secure if they could be marked—say, for instance, by trying little bits of blue ribbon upon them to distinguish them from the infinitude of vulgar multitudes of other germs everywhere around them. And it might be said that these germs did deserve such a token of distinction on account of the sober way in which they behave exactly according to what the commanders in the experiment expected of them. Indeed, if you will trail a little poetry amongst bacteria, they are so numerous and light that they will gather around and give body enough to the form of your conception so as to make good your theory and set it going in living shape; and a biological theory will have a very happy life when enclosed in a body of active germinal infective protoplasm. It is, indeed, the most fashionable creation of the period. But one must not speak irreverently of protoplasm, and our subject is all too serious. The question may appear a very narrow one when we ask

whether fever germs are independent parasitic organisms on the one hand, or specialized parts belonging to the human species originally taking their life from the human body. But to be stuffed with foreign germs is really so very different a thing from having your texture life set into new vital action by spermatic particles from the texture of another person, that it would be well to know which is the truth, if we can only find it out. As to the coarser view which has been advanced, to the effect that the merely mechanical action of fermentation germs may cause the phenomena and fatality of fever, we are not without an instance to show us what really are the consequences of the presence in immense numbers of microscopic organisms in the human blood. The recent discoveries concerning *filaria sanguinis hominis* show that these minute worms may exist in myriads and circulate with the blood without producing any fever, and, indeed, without causing any grave symptoms, and this when these worms are so numerous as to be immediately found in every drop of blood examined. Indeed, the history of *filaria sanguinis hominis* seems almost to give a crucial negative to any theory which would suppose fever to arise from a merely mechanical action of germs—that is, through mechanical obstruction produced by the germs. For when we thus speak of fever germs as perhaps always present in the blood, you must not suppose that one only has to get a microscope and a slide and put a little fever blood under it to find it full of germs. No, try in any of our cases of typhoid in the wards and you will find these germs by no means very easily discovered or obvious things. At the outset of such an inquiry you must take notice that the blood serum is often crowded with minute particles which must not be confounded with bacteria, and which exist often to a large extent in the blood of healthy persons. During last winter clinical session some of my most acute and intelligent friends, perhaps now present, searched carefully for germs in the blood of several severe typhoid cases. The result was that one bacterium was seen, only one, but I was told it was a very active one. When I say that Mr. Booth saw it, you will know it was well seen, for we all regard Mr. Booth as one of the very ablest and very best students at Guy's, but perhaps the main fact was that all were quite sure that there was only one bacterium. Next lecture we will take up in detail the consideration of the history of contagion.

Abstracts

OF

INTRODUCTORY LECTURES

DELIVERED AT THE

MEDICAL SCHOOLS OF LONDON

AT THE

Opening of the Session 1882-83.

ST. GEORGE'S HOSPITAL.

INTRODUCTORY ADDRESS BY DR. HERBERT WATNEY.

AFTER referring to the loss sustained by the medical school through the resignation of Dr. Barclay, the lecturer spoke of the new examination instituted by the Royal College of Surgeons to be held by the teachers of anatomy and physiology. He considered that it will be only a guide and help to the ordinary hardworking student, and will be so easy as not to discourage any, but will

prevent the first year of student life being partially wasted, as has sometimes been the case. A short account was then given of some of the sciences bearing on medicine. He said anatomy, the foundation of the medical sciences, can now be satisfactorily studied by all who enter our profession; but this has only been the case during the last hundred years. It is, however, a question whether the pendulum has not now swung a little too far; whether the examination in the minor details of anatomy, and, consequently, the teaching of these details, have not gone further than there is any need; whether the oldest science does not engross too much of the student's powers, not as regards its essential principles, but for its minutiae. And the very strong opinion of William Hunter was quoted to the same effect. Dr. Watney then dwelt on the importance of physiology and its fascination as a study, bringing us face to face as it does with the problems of life and death, and leading us to "the borderland of the material and the immaterial;" but he pointed out that the same evil of overrating the importance of minutiae is sometimes met with in this study, saying that there is a physiology whose devotees seem to think more of the instruments or the specimens, soon to be set aside for newer and better ones, than of the valuable observations obtainable by such means. Pathology was described as being at present divided into two great branches—one, which may be fairly classed as belonging to the two sciences of anatomy and physiology, dealing with the anatomical or physiological changes wrought in the body; the other quite different in its character, aiming at much deeper knowledge, seeking to discover the causes of certain diseases, even, it is said, cultivating these causes, and so controlling them that they become innocuous. It is probable that vaccination is a remarkable instance of this method of rendering a virulent poison harmless by means of a series of cultivations in the bodies of the lower animals. The great necessity for the study of pharmacology was next referred to, and the study of *materna medica* was alluded to as being only a "survival." The value of hygiene was then spoken of, and the change in the death-rate of the population during a number of years was considered a clear indication that hygiene is giving us most valuable aid in our struggle with disease. The lecturer remarked that during the time that the sciences bearing on the healing art have been developing, much work which may truly be called scientific has been accomplished in medicine and surgery; but we are still obliged in great measure to act from the basis of experience and from a knowledge which, though it has the authority of time, has never had a scientific foundation.

He then attempted to answer the question, What should be the due relationship between the scientific and the practical in the training of the student, and in his after-life as a medical man? After showing that there is generally an intimate union of these two apparently opposite principles in those whom we regard with the greatest respect, he proceeded: A scientific education implies study with a view to the acquisition of knowledge apart from any ulterior object—that is, seeking to know what has been accomplished in any subject, and to be so placed that future progress is possible, supposing that the patience and abilities of the individual are equal to such advance. It should, however, also include the acquisition of the scientific method. Practical education implies the study of any subject in such a manner that we can bring our knowledge to bear at the present or at a future time. The scientific worker is remarkable for his dissatisfaction with

the present state of our attainments and his desire to know more; further, he is noted for the accuracy of his knowledge, it may be only in a very limited field, but in that field he is not only aware of what has been discovered, but of the manner in which the discoveries were arrived at and the extremely unsatisfactory basis on which much of our supposed knowledge rests. On the other hand, the sympathies of the practical worker are with that portion of mankind which exists near and about him, and his energies and abilities are concentrated to produce, with the present fund of knowledge, the greatest results and the utmost benefit. He said it cannot be too strongly insisted on that the study of the sciences bearing on medicine will not alone enable you to become a safe guide in surgery or medicine; these last have to be studied, they have their methods and instruments of precision, some of which, such as chemical reagents, are well known to the chemist, others, as the thermometer, to the physicist, yet it is impossible for any physicist or chemist, or even for those who have studied the sciences more nearly allied to our profession, to understand the value of certain phenomena taken in conjunction with others, unless they have studied medicine itself. "Therefore, in answer to the question, What is to be the relationship between the scientific and the practical in your course of study? I would say, If you wish to follow the practice of medicine do not devote too much time to the study of the sciences. They are to be only portions of your education; they are the sources of much knowledge, but they are not the knowledge itself."

Dr. Watney then continued: "Science is not liked by some because it makes so little of the individual opinion, and treats so lightly that power which some men have of enforcing their views and persuading their fellow men. In politics and in art we see the immense influence of the individual—how his word is taken almost as law. Yet the habit of accepting without question what is told us has been the most fatal stumbling-block to the advance of medicine. The reputation of Galen helped to retard for centuries the advance of anatomy; and the deference paid to authority during the Middle Ages did incalculable injury to the large body of practitioners of that time, who learned to work in a mechanical, self-satisfied manner, impatient of any advance, unobservant, allowing centuries of time to pass and millions of sick folk to be under their hands, without attempting anything further than to struggle with one another as to who should be the greatest, 'seeking rather to conquer their opponents in argument than to penetrate the secrets of nature.'

"It is, however, easy, standing on the platform of our present knowledge, to point out the failures of the past generation, but the question which every thoughtful man will put to himself is, not what were their absurdities, their mistakes, but what can we learn from their failures? It is clear that ability will not prevent mistakes, and even absurdities; for many of the older practitioners were men of great genius, and we have no proof at all that there is more ability now than formerly, nor can anyone imagine that we take more pains than formerly were taken. Must we, then, assume that we have a better method? And yet who can say that he has a better method than Harvey? At last we are driven to the conclusion that medicine is a progressive science, and that we are profiting by the information obtained by others, reaping the fruit sown by them at great expense, after many failures and much disappointment.

"Now, with regard to the question, What is to be the relationship between the scientific and the practical in your future life? I would urge that

everyone who practices the medical profession should, besides his ordinary avocations, work in a scientific manner at some subject, and aid in the advance of knowledge. It is very necessary that you start with one humbling thought, that you cannot finish your studies, and that you must go into practice to a certain extent incompletely prepared. It is impossible that you should be a good anatomist, or physiologist, or pathologist, or a good practitioner, when you leave this or any other school of medicine. It has lately been debated whether four years are enough for study, and whether the curriculum ought not to extend over five years. Surely ten years would not be enough to master anatomy and physiology alone, and by the end of that time so many advances would have been made that you would hardly be able to keep your knowledge current with the times; thus physiology is being split up into various departments, and few are skilled alike in physiological chemistry, in experimental physiology, and in the use of the microscope. If you grieve at the thought that your knowledge must necessarily be imperfect, console yourselves with the fact that it is found, in planting trees in exposed and windy situations, that it is necessary to take quite young and small ones, for that the older and taller trees, which have had the advantage of good surroundings and have been accustomed for a long time to cling to their supports, do not grow so well in such situations as shorter trees, which, though smaller when first put in, eventually become more vigorous. So the well-taught but not too fully-taught student, though at first he may seem behind the artificially-forced stripling, will send his roots down deeper, and obtain a firmer hold in any new undertaking he may choose. And you are sure of true success. Your aim will be to allay pain, to prevent the effects of wrong-doing, and to combat death. It is true your patients will suffer for their follies, will at times be wrung by pain, and will, at length, all die; yet you will be successful, because you will not set before yourselves, or others, the false chimera that you can finally resist death, or prevent its painful accompaniments. You will accomplish what you hoped to do—alleviate pain, in a great measure prevent the effects of evil, and delay the advent of death himself. Yes, you will succeed; but let not that be our only success, great as it may be. We may look forward to the time when we shall meet Him and be with Him who alone has conquered pain and sin and death, and who has won a complete success for us."

LONDON HOSPITAL.

ADDRESS BY MR. JONATHAN HUTCHINSON.

THE address of Mr. Hutchinson was given at the conversazione, and was devoted almost entirely to a sketch of the life of Thomas Carlyle, with a critical survey of his work.

"About a year ago there appeared," said the lecturer, "immediately after the death of one who was perhaps, take him for all in all, the greatest man of the present generation, two volumes of Reminiscences. In these we found amongst much that we valued much also that needed excuse, and some things that it was hard to forgive. Those, however, who were most pained by certain passages in that work will, I cannot but think, have been greatly relieved by the reading of the two volumes of biography which Mr. Froude has just given us. In these latter we have, full and complete, the story of Carlyle's life, his struggle, and his victory; and the hero now again claims, if I mistake not, that lofty position in our estimation from which he had been almost threatened with

dethronement. Here we are permitted to see, in full disclosure, the sources alike of his weakness and his strength, and our marvel at the work which he did, and at the uses to which he put his troubled life, rises higher than ever. The unconquerable independence, the industry, the faith in the future, unclouded in the main by the deep-rooted melancholy of his nature, the sense of duty in his work, are features in which the character of Carlyle attain sublimity. His letters to his wife and to his mother, and perhaps above all those to his brother John, claim our admiration in the very highest degree. Especially to all young men, and to all young medical men, for they were addressed to a struggling young physician, I would commend his letters to his brother. Over and over again, in his letters to his brother and in his entries in his own diary, Carlyle enforces the paramount duty of keeping clear of the 'gig-man' spirit. In one of his most pathetic letters to his wife, when their prospects were at the lowest, and he is endeavoring to incite her fortitude to further effort, he reminds her with pride that her soul was never that of a 'gig-manness.' The words in question are designed to note merit and respectability as indicated by externals alone and without regard to the inner character of the man. To be above the gig-man spirit is to be capable of maintaining our proper position in the forum of our own feelings irrespective of success in life, and to be in the habit of according such position to others quite irrespective of theirs. It is to take measure of the soul rather than of the body's trappings. There is yet another word frequently occurring in these letters which it may be necessary to explain. It is the German word *entsagen*. Carlyle repeatedly congratulates his brother on having learnt the meaning of this word, and in one place he writes 'My main comfort about you is to see the grand practical lesson of *Entsagen* impressing itself in ineffaceable devoutness on your heart.' He regards *entsagen*, he says, as the first lesson in all true life. With Mr. Froude's help we may interpret his meaning to be that we should in the first place learn the doctrine of renunciation of worldly gains and become able to say firmly that we can do without any and all of the various pleasant things with which the world usually rewards those who render services to it. It is, in fact, to learn, as we find it expressed in 'Sartor Resartus' 'to do without happiness and to find in its stead blessedness.' Were we to attempt to sum up in brief the secret of Carlyle's strength, I think we should have to say that it consisted in his perception of the reality of things. This was a feeling which was ever present with him. Men were real to him, spirit-possessing beings, never wholly without the capability of affection, never even in the degraded condition of partridge-shooters or gig-men, losing all share in the divine element of life. Their differences, too, were real and must be taken carefully into account. The world was real, the universe real, the past had really been, and the future would most certainly come. In truth, this sort of perception is the secret of strength in us all, and its absence is the cause of all weakness. It is the very basis of all motive and of all effort. It measures our devotion to truth and our belief in its value, upon it is rooted the distrust of all shams, the hatred of all forms of lying. The gospel of duty, self-restraint, and devotion to work, was one which Carlyle had well learned, perhaps no man ever better. But there was a great failing in his attainments, one which marred the happiness of his life, and which not only robbed him of the reward which was his due, but considerably diminished the usefulness of his teaching. He had not learned what we may, I think,

without irreverence style the Religion of Patience. By patience I mean not the mere passive virtue of endurance, which indeed is not unfrequently no virtue; I mean rather the ability, when we have done our best, under all possible circumstances to rest undesperingly and trustfully for the result. Dare I venture for one moment to assume the prophet's mantle myself, I would foretell that the worship of patience in this exalted sense is one upon which the present age is about to enter. If we glance back over the great mythologies of the past and note their hidden meanings, we shall observe the worship under various types, of various forms of power, of beauty, and of virtue. In the earliest ages the gods were symbols of force; they did, and not always beneficently, the great deeds which controlled the destinies of men. Next, as in such types as that of Hercules, we see force combined with human-heartedness, but still force, gross and almost purely physical in its efforts. Side by side with this sprang up the worship of beauty, especially in human and female forms, and the shrines of Juno, Minerva, and Venus, under various names in different climes, claimed their countless votaries. As the moral sense grew and human sympathy expanded, the unsatisfying nature of these Religions of the external became felt and the world witnessed events such as the self-renunciation of Buddha and the advent of what has been well termed the Worship of Sorrow. In these sublimely loving creeds there were, however, elements of weakness and of unfitness for the everyday work of the world, and the pendulum of human sentiment, as it was sure to do, swung back again towards an exaggerated estimate of physical force and natural beauty. In truth, the worship of these was far too deeply rooted in our very being for it to have ever been put aside. The other had been added, but these had not been dethroned. Nor will the introduction of a new goddess effect the displacement of any one of her predecessors. We may pay vows at the altar of patience without ceasing also to render due homage to courage, energy, and physical vigor, and without bating one jot of our admiration for the charms of external beauty, or of our reverence for that glory of soul which can find the happiness of life in pouring blessings on others. Part of Carlyle's impatience was creditable, being due to the greatness of his nature in other directions, his keen appreciation of the true making him correspondingly intolerant of what seemed to him false. This topic of life-patience is one which concerns us as medical men, perhaps, more directly than some of the others which I have mentioned. To a large extent impatience of life in its various forms—acute, chronic, and paroxysmal—is undoubtedly a result of inherited organization or of derangement of health. Its cure, if cure there can be, must be sought from physical means, and not from any new development of opinion or fresh insight into the order of the universe. That, however, the influence of opinion and of creed upon the mental health is often very great, no one knows better than the medical observer. I have said that Carlyle was impatient, and that he formed, under the influence of prejudice, very unjust opinions on some topics. Amongst others, he spoke of the doctrines of Darwin as too contemptible to be worth a moment's consideration. In putting them thus scornfully aside, I think he missed a main source of comfort in life. The truth is that what Carlyle himself was proclaiming in the language of the mystic, Charles Darwin was explaining in the language of science. Carlyle was asserting that there is a spiritual power in nature, was bidding us reverence that power as supernatural, and as working through rough and

mysterious ways towards certain and definite good. Darwin, looking at the same facts from a biologist's standpoint, explained how this result did indeed come about, and that, too, through the simplest and most unmythological ways. It has been thought by many, by believers as well as sceptics, that Darwin's explanations are melancholy ones, and that they would in short land us again in regions of mere brute force. I cannot think that this view is correct. Darwin did not impose any new 'law,' he simply interpreted the facts of nature, and nature, whether his explanations be true or false, will go on in the future as it has done in the past. Many ages have had their prophets and their seers, those who in the uttermost earnest have set themselves to deliver the messages with which they have been entrusted. If I am not mistaken, however, no age and no country has been more favored in this respect than our own. I will name to you four, not that they are the only ones, but rather that they stand foremost, and because, also, I think they may be fitly held to represent the four divisions of social religion to which I have referred. To Carlyle, of course, we give the chief place, and to him we assign the priesthood of the worship of Strength. There can be not the slightest doubt as to whom I ought to name as our Seer of the Beautiful. What Carlyle has done for the worship of Strength, his pupil, John Ruskin, has done for that of Beauty. To Wordsworth must, I think, be assigned the office of latter-day priest at the shrine of self-renunciation and human sympathy. If we go to Wordsworth to learn sympathy, we must, I think, turn to another poet for initiation into the cultus of Life-patience. In this noble worship, if I mistake not, Robert Browning stands as chief priest."

His reasons for the above selections having been set forth, Mr. Hutchinson concluded as follows:—"Now, gentlemen, students of our college, in conclusion, I can but hope that none of you will consider that I have unduly neglected an opportunity of speaking to you on subjects directly pertaining to your education. I hope to have other opportunities for doing that. It has seemed best this evening to address you on topics which concern us all as men. I might have devoted the hour to eulogy of the profession which you have chosen, but surely it needs no praise. So, also, I might have praised the school which you have selected, and paid compliments which would have been very sincere, however blunt, to those at present concerned in its management and to my colleagues. But here, again, facts speak for themselves, and you are familiar with them. I have preferred to try to find you motives for work and to give you strength and confidence in study. If now I were to sum up in one sentence what I have been enforcing it would be this: the secret of all noble life lies in belief, and the characteristic of all noble minds is the vigor with which they believe that which is true. Try to attain belief in the reality of all things, so shall you never want for motives, so shall you be able to live and work without hurry and without sloth. Finally, permit me to commend to you this formula: prize strength, love the beautiful, practice self-denial, and be patient."

MIDDLESEX HOSPITAL.

INTRODUCTORY LECTURE BY DR. CAYLEY.

DR. CAYLEY commenced by alluding to the great calamity which had just occurred, and said: "A blow has fallen upon us so suddenly in the death of Dr. Lyell, who was to have delivered the address to-day, that we are unable as yet to estimate the extent of our loss. When we remember his

great abilities, his untiring industry, and his blameless and pure life, we feel the bereavement great indeed. We are, however, in the position of soldiers on the field of battle, where if one is struck down there is no time to indulge in lamentations, and like them we must close up the ranks; and although we must feel the proceedings of to-day to be indeed clouded with gloom, we must endeavor as far as we can to go through the necessary business and not allow the occasion to pass without a few words of advice to students from their teachers."

After referring to the object of the meeting, and wishing "God-speed" to the neophytes in medicine, the lecturer went on to notice the various points of view from which medicine may be regarded; first, as a science, in which they investigated the growth, structure, and functions of the human body, and the various causes by which it was disturbed; next, as a practical art in relation to the cure of disease and all the means for its prevention; and, lastly, as a profession in which those who entered it might hope to pass an honorable career. Of all these objects the one most liable to misapprehension, especially on the part of the outside world, was the scientific one. The pursuit of knowledge in a scientific spirit aimed at the investigation of natural laws rather than any immediate practical advantage. Medicine was now threatened with a new danger, the arrest of experimental research, and it behoved the profession to meet the arguments of their opponents and to defend the cause which they believed to be so essential to the welfare of mankind. The objections raised to experimental research were based upon a misconception of the whole system of nature. We see through the whole domain of life an interecine struggle for existence, and man himself extirpates without scruple those animals he finds injurious to his predominance. He kills them for clothing and food, makes slaves of them, and slaughters them by thousands for mere amusement. If Harvey had lived in the time of Victoria (instead of that of Charles the First), under the present restriction he would never have discovered the circulation of the blood, whilst the deer upon which he would have experimented would probably have been hunted to death by the royal stag hounds. Turning to the practical side of medicine, the lecturer impressed on the students the fact, that their profession required all their energies in the study of its various branches, and in the ordeal of examinations. He counselled them to let this pursuit be foremost in their thoughts, so that they might not devote too much time to mere amusement. Many people thought the medical profession was overlooked in the distribution of honors, but they were cut off from the main source of honor—e.g., high office in the State—which was beyond their sphere of activity. Neither were they in a position to acquire wealth, but must be satisfied with obtaining a competency. On the other hand, into whatever house they entered they went for the benefit of the sick, and they would win not only the respect, but the esteem and love of their fellow citizens. If so fortunate as to acquire this, they might well let the rest go, and they should so spend their time as to be worthy of the hospital in which they had been trained, and of the country of which they were citizens.

ST. MARY'S HOSPITAL.

INTRODUCTORY ADDRESS BY DR. THOMAS KING CHAMBERS.

THE lecturer began by saying that an "introductory" is usually delivered by some active

junior member of the staff, who has at his fingers' ends all the special advantages which a new pupil at St. Mary's inherits. He, however, had not that personal experience now, and, in fact, was saying the farewell to his old chair, which illness prevented him saying a few years ago. He had, therefore, selected as his subject "The Relation of the Medical Student to the General Medical Council." He was the junior member of that mysterious body, and therefore supposed to be a proper person to introduce it. The Medical Council's most important duty is to watch over the student, to see that he gets justly that education for which he gives his time and money, to show him the path by which he may become a useful and honored Englishman, and to make that path as easy and direct as possible. That the Council is performing this duty is graphically shown by contrasting the medical student as described—and truly described—by Charles Dickens, and the medical student of to-day. "I will take this opportunity of giving you a few words of warning. Do not on any consideration make the mistake of accepting places as assistants before you have passed the qualifying examinations. By so doing you will be mixing yourselves up with a set of men who have lost all ambition of being legitimate practitioners, who have degenerated into mere drudges, whose manners and morals and education unfit them to be your companions. You run great risk of becoming like them and being equally despised; and by delaying your fitness for going up to your final examination, you are making your education more tedious, and therefore more expensive in the end. But when you have cleared examining boards off your minds, then, indeed, I do not know a more valuable part of education than that which can be got by a good assistantship. For having learnt systematically and thoroughly how to learn, you will understand quickly the details of the application of your knowledge and profit in direct proportion as you have not muddled your brains with those details beforehand. They are selfish and cruel persons who tempt you to be unqualified assistants. They do it for their own dirty profit, and it is a very bad bargain for you." Dr. Chambers then pointed out that a very great portion of this improvement of the *status* and comfort of the medical student was due to the action of the Medical Council in forcing upon parents and guardians the duty of giving a sound preliminary education to those destined for the profession. "When a student feels the satisfaction of ease in acquiring technical knowledge and a fitness for belonging to the cultured classes which early education bestows, he should not forget his indebtedness for it to the Medical Council. To the influence of the Medical Council is also due another great comfort to the student—the substitution of several examinations for that one which used to hang like a sword of Damocles over his whole career. Perhaps some may exclaim that this is worse and worse—it is the hanging up of several swords instead of one. But that is a superficial view of the matter. It is in reality a 'dilution' of the single examination, which spread over several years ceases to be a legitimate object of fear altogether. If an old man's pupilage could come over again he would certainly choose that body to examine him which most divided its examinations; for he knows that he would eat, drink, and sleep the better for his choice. Then, the curricula of the different licensing boards have been the subject of serious thought and arrangements by the Council. They are made as harmonious and as equal as possible. The student may rest assured that by following them strictly and honestly he will be making the best use of his time to ensure success in

the examinations; and success in the examinations is a pledge to you that you have those qualities which lead to success in after life. Do not, my dear fellow teachers, take umbrage at what I have said as to the need of keeping examinations constantly in view. Observe the signs of the times; examination, as an engine of education, is becoming more and more powerful, and, wisely or unwisely, all orders of men are agreed in reposing their confidence in it. Trust has begotten a resolve to deserve trust; and I feel sure that the schemes of instruction suggested by the medical examining boards and approved by the Council are the best guides we can have. Your responsibility is very great; yet it is not too great to be borne by the exercise of the simple commercial virtues of (1) sobriety, (2) punctuality, and (3) attention to business. Let your 'sobriety' be known unto all men in deed, in thought, and in speech. Words, as Homer tells us, have wings, and they fly to the ends of the earth. You can hardly fail to have been startled, if not awestruck, by the quotation of some chance sentence of yours out of a lecture or conversation in the mouth of an old pupil or pupil's pupil; it may reappear in the colonies or come back from America. Take care, then, that it is a true message which thus travels forth. Avoid all paradox, exaggeration, or inexact illustration, however brilliant. Be assured it will haunt you, and start up when you least desire. 'Punctuality' is the homeliest of virtues, but the neglect of it by teachers is visited with very public loss of reputation. Pray remember that every minute students are kept in waiting is most likely occupied in criticising you, and in commenting, not favorably, sometimes not quite fairly, upon your person, your manners, and your teaching. I will leave you to judge if that conduces to your influence for good. 'Attention to business' is an expression which seems to demand an opinion as to what your chief business is. You will, of course, say it is to make pupils into the best and safest practitioners that the time afforded us allows of their being made. Yet teachers differ somewhat as to the surest mode of attaining this end, and, possibly, some of you may dissent from my concluding sentences. A frank submission to the mastery of the inevitable examiner is, I am sure, the wisest course, and I expect this will lead in the end to changes in our method of communicating instruction. It must gradually become less professorial and more catechetical or tutorial. I mean that a considerable part of the time devoted to each study should be occupied in question and answer on matter previously prepared by the class. The subject should be explained and enforced from the chair; not, as of old, given out fresh from the chair and learnt up by notes afterwards. The catechetical method gives a shrewdness in catching the point of a question and a facility in answering it which contribute greatly to success in examinations and to readiness in the emergencies of future life, and by bringing their two minds into more immediate contact it gives the teacher a power of measuring the progress and declaring when sufficient advance has been made to sanction the issue of a certificate of sufficient attendance. To try to gain this early would be a sharp spur to early diligence, and would ensure the presence of minds as well as bodies on the benches of our theatre. Students complain, not entirely without reason, of the number of lectures they have to sit out and of the days broken up into fragments and consumed. If you adopted this plan the remedy would be in the complainers' own hands, for he would only have to show a mastery of his subject to be free for the rest of the session and give his time to reading and ward-study. I am satisfied, by observation

not limited to medical schools, that the catechetical is, of all methods, the most sure and effectual for teaching Englishmen. I should not have dared to say so much had I not observed tentative efforts made here to introduce the principle I have advocated. To succeed, the efforts must be combined, and, my new young friends, they must be co-operative; assistance on your part, hearty and forbearing, must be given, or the experiment will not be a fair one." The lecturer then took leave of the theatre, where, he said, he had begun to lecture before the plaster was quite dry upon its walls, and where he left one of his first pupils as his successor.

WESTMINSTER HOSPITAL.

INTRODUCTORY ADDRESS BY DR. DE HAVILLAND HALL.

AFTER expressing his approval of the custom of opening the session by addressing a few words of advice to the students who are commencing their medical studies, of encouragement to those already known, and of farewell to those about to take flight from their alma mater, Dr. Hall pointed out some of the advantages of a small school. He thought that Westminster had deserved well of several of its larger rivals, and cited the names of men formerly on its staff who had migrated to other hospitals carrying with them the experience they had acquired at Westminster. It should not be forgotten that, in the language of one of the old reports, Westminster is "the parent of all the medical and surgical charities of these kingdoms that are supported by voluntary contribution." Then, addressing the students who had just entered, Dr. Hall pointed out the necessity of settling down to work steadily if they would avoid the temptations incidental to the life of a medical student. The lecturer regarded the examination at the end of the first year, recently instituted by the Royal College of Surgeons, as likely to be a useful check to the lazy student, and serve as a beneficial stimulus to all. In insisting upon the mental discipline of a thorough course of anatomy, and the habit of exactitude fostered thereby, he said that it was the anatomy learnt by actual dissection which was required, and not the counterfeit obtained by the aid of cram-books and tips. He therefore advised that every opportunity of dissecting should be seized, so as to get a practical knowledge of the subject as well as to acquire the manual dexterity, which he stated to be almost as important to the physician as to the surgeon. Dr. Hall discountenanced attendance in the out-patient rooms and wards before the primary examinations had been passed. "If you begin to go round the wards before you are capable of understanding and taking an intelligent interest in what you see and hear, you will in all probability acquire the habit of doing things in a casual manner, which is destructive to anything like thoroughness." He therefore advised that only the minimum amount of attention required by the regulations of the College of Surgeons should be devoted to surgery until the primary examinations had been passed. He urged all students to make an effort to pass the first examination of the Royal Colleges of Physicians and Surgeons within the first two years, so as to leave two whole years for the practical part of their studies. He also insisted upon the importance of students having a clear understanding as to what degrees or diplomas they intend taking. "Much time is lost and inconvenience caused by the student discovering, after he has started on his career, that he requires a degree in medicine, or that the Fellowship of the College of Surgeons will be necessary. When you are once launched into practice it will be almost impossible for you

to obtain a British medical degree (unless you be over forty), as all the universities except the London require residence, and the curriculum of the latter puts that out of the question." Dr. Hall was distinctly in favor of enforcing attendance at lectures; he considered that lectures could lay stress on the more important points, and that in such a progressive science as medicine attendance at lectures was the only feasible way for students to keep abreast with the daily increase of knowledge. He advocated the plan of taking short notes at lectures, to be amplified at night. In speaking of the necessity of thoroughness, he said: "If you begin your medical career with an inaccurate knowledge of the sciences on which medicine is based be sure that you will never practice your profession with anything like satisfaction to yourself or advantage to your patients. At the best you will be little better than empirics."

"Of equal importance with the mental training is the necessity of seeing that the physical needs of the body receive their due share of attention." In speaking on this subject Dr. Hall drew attention to the demands upon a medical man's energy and decision, and to the importance of good health, unless the doctor is himself to fall a victim to the very disease he was called upon to treat. As a means of preserving health regular exercise was highly praised, and students were advised as much as possible to make their recreations such as would take them into the open air, and to avoid the billiard-room. In speaking of purity of life, Dr. Hall said: "If your purview is limited to this world only it is worth your while to lead a moral life. Infringements of the moral law are frequently visited, as, alas! you will too often have an opportunity of seeing, by immediate punishment, and by what I consider as more awful a punishment, which in certain cases is shared by innocent victims. Ruined health, early death, or premature old age, to say nothing of the misery and wretchedness communicated or transmitted to those nearest and dearest, have been in many instances the lot of youth who commenced life with bright prospects; so true is the apostolic saying, 'The wages of sin is death.'"

After a few words of caution as to the choice of friends and on the means of keeping out of the way of temptation by being always busy, Dr. Hall proceeded to discuss the different openings possible to the medical man. He assumed that the majority of his hearers were destined for general practice, and he told them that with fair education, good health, and tact, they might rest content that they would earn for themselves a living, and in many cases a very comfortable one. He strongly advised those who were intended for general practice to go as assistants for a time before starting on their own account, so as to learn something of the requirements of general practice. He then spoke of different modes of starting in practice. Those who were anxious to see something of the world before settling down had a wide field of choice—i.e., there were travelling appointments to be had or surgeoncies in the mercantile or emigration services. For those who wished for work of a still more permanent character, the three branches of Her Majesty's service were open—viz., the Army Medical Department, the Indian Medical and the Naval Services. "Ten years ago and less the Indian Medical Service was the only one which attracted good men; the two other services were literally starved. But of late years, owing to the increased pay and improved regulations, there has been a keen competition for all these services. For instance, at the last examination, held in August, there were ten vacancies for the army and thirty candidates, the same number of vacancies for the

navy and twenty candidates, whereas for the eight vacancies in the Indian Medical Service there were forty candidates." Dr. Hall then discussed the respective advantages of the different services, and pointed out that there was ample scope for scientific workers in the department of public health. After reading the Hippocratic oath in *extenso*, he concluded his address as follows:—"The enlightened morality of the oath, and the admirable rules laid down in it for the conduct of the medical man towards his patient, leave little to be desired, and if you only act up to the spirit of this document, over two thousand years old, you will attain, if not wealth, at all events the respect and esteem of all with whom you come in contact, and a happy hereafter."

Original Papers.

REMARKS UPON THE OSSEOUS LESIONS OF LOCOMOTOR ATAXY,

WITH A CASE SIMULATING MALIGNANT DISEASE.

By J. ALEX. WILLIAMS, M.B., M.R.C.S.,

House-Surgeon to the Royal Portsmouth Hospital; Late House-Physician to the London Hospital.

THE conspicuous absence from our museums, previous to the researches of Charcot, of specimens illustrating the osseous and articular lesions of locomotor ataxy, induced Sir James Paget¹ during the meeting of the late International Congress to ask Professor Charcot, "Whether these are not instances of a disease which has lately for the first time appeared, or at least has lately become much more frequent than formerly it was?" Now with all due deference to so great an authority, I cannot but think that their more frequent recognition in modern times is mainly owing to the increased facilities afforded us for the diagnosis of the disease in its early or pre-ataxic stage, and this is chiefly due to the labors of Duchenne, Westphal, Erb, Hutchinson, Jackson, Charcot, Buzzard, Robertson, and many others. For Professor Erb² writes, "this arthropathy is most common in the early stages of tabes, and chiefly in the preliminary period before the ataxic disturbances of motion have appeared, and when the lancinating pains constitute the chief feature of the complaint," and this assertion I believe holds good for the osseous lesions. Hence it is highly probable before the diagnostic significance of "lightning pains," ocular paresis, and Westphal's symptom were known, that many cases presenting tabetic arthropathies, or osseous lesions, were diagnosed as examples of rheumatoid arthritis, or of malignant disease of bone, etc., as might easily have been done in the case now recorded. The frequency with which patients describe their pains as "rheumatic" is strong presumption in favor of this view. Dr. Hughlings-Jackson,³ referring to a case of tabes whose only symptom besides lightning pains was the Argyll-Robertson pupil, says "the case might be taken for one of neuralgia only by those who have not studied lightning pains, and who do not examine the pupils." Dr. Buzzard in a footnote to his paper⁴ upon the subject, says, referring

to the arthropathies, "In most of those which I have published, the nature of the underlying disease had never been suspected." He instances a case in which excision of the knee-joint was very nearly performed in a surgical ward of a hospital; also of two other patients, inmates of surgical wards, who had been exhibited to candidates at an examination for a diploma as examples of rheumatoid arthritis. Charcot, in answer to a remark of this same authority, complaining of their rarity in England, said, "You will find them in the workhouse infirmaries, and in the surgical wards of hospitals." How true this remark was recorded cases testify.

In addition to the case I am about to record, in which, although the tabetic symptoms were recognized, a diagnosis of malignant disease was nearly completed and operative procedures almost resorted to, I can remember the case of a middle-aged man who came under my observation for incontinence of urine, at a time when I was house-physician to Dr. Gilbert Smith at the London Hospital, under whose care he was admitted. Here none of the ordinary causes of incontinence could be found, but the right hip-joint was much enlarged and disorganized by large irregular bony outgrowths, which also projected into the pelvis. The patient, a dull stupid man, had never before noticed the enlargement around the joint, but he walked lame with that foot. On inquiry into his history it was found that his lameness dated from an injury received some six or seven years previously, in which he said his hip had been dislocated by its entanglement in a cart wheel. Further inquiries elicited the fact that he was the subject of marked ataxic symptoms; thus he had been subject for many years to sciatica, his pupils presented the Argyll-Robertson phenomenon, and there was a total absence of knee-jerk in both knees. He walked with the aid of a stick, and had a somewhat ataxic strut, which, however, might have been due to his lameness. The eyesight was not affected, and so far as I remember the optic discs were normal. There had been no gastric crises. He was seen by Dr. Jackson and Mr. Hutchinson, both of whom confirmed Dr. Smith's diagnosis of ataxy, and considered the osseous material surrounding the joint to be unabsorbed callus, produced in excess in an ataxic patient, as a result of previous injury to the femur close to its neck. Now, such a case, in the event of the pain not having been inquired after, and the eye and knee phenomena not tested, might readily have passed for a severe example of rheumatic arthritis, or even of malignant disease of the bone.

From the analogy which these trophic changes in bones and joints present to the arrest of the growth of bones often observed in infantile paralysis, they have been assumed by Charcot to be due to implication of the anterior cornua of the grey matter in the sclerotic process. Buzzard, on the other hand, having observed gastric crises to be more frequent in these cases, has suggested sclerosal invasion of the roots of the vagus nerve as the cause of the altered nutrition in the osseous system. Neither of these theories, however, has been satisfactorily borne out by anatomical observations, and it is to be noted that in neither of the cases here referred to were gastric crises observed. Charcot, when demonstrating the arthropathies upon the wax model of Berthelot, before the late International Medical Congress, remarked⁵ that "fracture of the bones and diseases of the joints appear to belong to the same pathological condition—i.e., when the disease attacks the diaphyses of the bone, the atrophy is proved by fracture;

when it attacks the joints, we get the wasting of the head of the bone with erosion of the surface." In this case nearly all the larger articulations were affected, and there was an excessive production of callus around an old fracture of the right pelvic bone upon its inner surface. In the main these arthropathies are characterized by a rapid and sudden effusion of serous fluid into a joint, the knee most frequently, usually unattended by inflammatory symptoms, but followed by rapid erosion and absorption of the articular extremities, with relaxation or destruction of ligaments; the joint becomes flail-like, and dislocations readily occur. Such a condition might readily be mistaken for a simple hydrops articulari were the ataxic symptoms neglected. The swelling is never entirely confined to the joint itself, but is diffuse and often extends over the entire extremity, and large osseous outgrowths often occur around implicated joints. The rapidity with which these changes are produced in ataxy is peculiar, a few days sometimes sufficing for the complete destruction of a joint (Buzzard). Osseous lesions often coexist with arthropathies, and *vice versa*. They are characterized by abnormal brittleness of bone, due to a rarefying osteitis, whereby the Haversian canals become abnormally widened at the expense of the osseous matrix—as a result spontaneous fractures from the slightest movements, such as turning in bed, etc., are of frequent occurrence. These fractures seem to possess great reparative power, and "it is common to find a more than usually exuberant callus thrown out" (Buzzard). This statement is typically illustrated by the following case, in which from slight muscular exertion the right femur became spontaneously fractured, rapidly followed by an excessive production of callus, causing great swelling of the affected thigh, and in its clinical aspects closely simulating malignant disease.

Philip H—, aged forty, street musician, was readmitted into the Royal Portsmouth Hospital on July 2nd, 1882, under the care of Mr. Rundle, with a fracture of the right femur. He gave the following account of his accident:—On April 23rd, when taking off his boot, he crossed the right leg over the left knee, but meeting with some difficulty in pulling at the boot, he gave the "leg an ugly strain," producing what on admission, the same evening, proved to be a transverse fracture of the right femur at the junction of its middle and lower thirds. The fracture was treated with plaster-of-Paris splint encasing the foot, thigh, and pelvis, and thus far successfully that on June 18th there was good bony union, and he was discharged cured, the leg for a short distance above and below the site of fracture being encased in a short plaster-of-Paris splint. No excess of callus was then observed. When at home, he said everything progressed satisfactorily, and, with the exception of slight pain beneath the splint, he had nothing to complain of. In about a week he discontinued the use of the splint, but remained cautious in his movements upon crutches. On July 1st, in walking across his room, he incautiously placed his body weight upon the injured leg, and immediately felt it give way beneath him. Next day, when brought to the hospital, he was found to have refractured his right femur at the seat of the former lesion. Next morning (July 3rd) the limb was observed to be much swollen, and very painful. In its lower two-thirds the femur appeared immensely thickened, by a hard and osseous feeling material, which below terminated abruptly at the knee-joint, posteriorly the popliteal space was almost entirely filled by a similar material; above the thickening gradually terminated so that the upper third of the femur felt normal. The super-

⁵ Transactions, vol. i., p. 128.

ficial veins of the thigh were very conspicuous; but the inguinal glands were not enlarged. Circumferential measurements of the thighs in different positions showed a great increase in the size of the right thigh, thus:—

	Just above the knee.	Middle of shaft.	Level of groin.
Left thigh, 12 in.	15½ in.	19 in.	
Right " 16 "	18½ "	19½ "	

On inquiry into the general history of the patient the following was ascertained:—He had formerly been a cork-cutter by trade, but for the last six years has been blind, and has since earned his living by playing the concertina. When seven years of age a "gristly" tumour was removed from over the right inner malleolus, the scar of which is still visible. When fourteen years old he had a bubo in the right groin. He denied syphilis, but in addition to the scar in the groin he has numerous coppery scars on both shins and spots on the chest, and, besides, presented well-marked ataxic symptoms. Thus: he has been subject to sciatica for the last seven years. His eyesight failed him six years ago; it commenced as dimness of sight, which gradually got worse, so that he is now totally blind, even to the discernment of light. During the last two years he has walked badly; "staggers slightly;" this he attributed to his blindness. When in hospital it was observed that the pupils were unequal, the left being about the size of a No. 9, the right about the size of a No. 6 catheter on the English gauge. They presented the Argyll-Robertson phenomena—inactive to light, active during accommodation. There was well-marked white atrophy of both optic discs, and an entire absence of knee-jerk in the left knee; that in the right could not be tested on account of the fracture. There were no gastric crises. On account of the condition of the limb, malignant disease of the bone being suspected, no further treatment than placing the legs between sand bags was deemed necessary. It subsequently increased still further in size, and on July 5th attained its maximum measurements of: above the knee, 17½ in.; middle of shaft, 19½ in.; level of groin, 20 in. On July 17th, iodide of potassium was prescribed internally, and oleate of mercury unguents applied locally. The limb, then, contrary to expectation, decreased gradually in size, and firm osseous union between the fractured ends resulted, so that on Sept. 23rd he was again discharged cured. At this time the limb measured: above the knee, 15 in.; middle of shaft, 17½ in.; level of groin, 19 in. There was still a large amount of unabsorbed callus surrounding the femur, most evident at the site of fracture and in the popliteal space. As a precaution, the limb was encased from the toes upwards in a stout plaster-of-Paris splint, and the patient warned to be very cautious in his movements and to use crutches.—Oct. 27th: Visited the patient at his home. He walks with aid of a stick, and has discontinued the use of a splint for two weeks past. The right knee, he says, feels very weak, and the ligaments are somewhat relaxed. Both knees present Westphal's symptom. The swelling of thigh has slightly decreased since last observation; it now measures: above the knee, 14½ in.; middle of shaft, 16 in.; level of groin 19 in. There is still great excess of callus around lower two-thirds of femur, the upper third still being free. No glandular enlargements. The right foot has become cedematous during the last month probably due to pressure upon the veins by the callus. The other symptoms are unaltered, and the fracture is firmly united.

Remarks.—This case affords a good illustration of most of the points previously referred to in

the paper. The difficulties attending a correct diagnosis were such that at one time a consultation of the hospital staff was held to consider the advisability of amputation for malignant disease. Recognizing, however, the difficulties attending the case in the absence of cachexia, glandular enlargements, and signs of secondary deposits it was thought best to watch its progress for a short period before resorting to operative procedure. The wisdom of this decision was subsequently proved by the slow but steady decrease in the swelling, and the unexpected repair of the fracture. The changes, in fact, so far as the callus was concerned, were regressive and reparative, not progressive and destructive, as in carcinoma, etc. It will be observed that the ataxic symptoms present were those which mainly belong to the pre-ataxic stage and were such that had the ocular and Westphal's symptoms been neglected the ataxy must have remained undiagnosed. Another noteworthy feature was the rapidity with which the callus was thrown out, for immediately after the second fracture when carefully examined by Mr. Olermont, the surgeon to the out-patients, no abnormal excess of callus or osseous material was observed. Yet forty-eight hours afterwards (July 3rd) when I first examined him there was then found a very excessive formation of callus as recorded in the notes. This fact becomes of special interest when we consider Buzzard's statement, previously referred to, regarding the rapidity with which the joints are sometimes destroyed in these cases.

For permission to record this case I am indebted to Mr. Rundle, under whose care he was admitted, and for many of the notes to my friend Mr. Cooke, the dresser to the case.

Portsmouth.

OIL OF TURPENTINE IN EGYPTIAN ENDEMIC HÆMATURIA (BILHARZIA HÆMATOBIA).

By JOHN WORTABET, M.D.,

Physician to the Hospital of the Knights of St. John, Beyrout, Syria.

My attention was first drawn to endemic hæmaturia about five years ago. Since that date I had seen six cases, three of which I had under close observation for some time in the hospital, affording me a good opportunity of studying the disease and trying different methods of treatment. I am induced to give the results of this study with the hope that they may be useful to the surgeons of the British army now in Egypt, where they may have occasion to see and treat the disease. I shall first give the notes of my last case, in which the oil of turpentine produced a complete cure, and then offer some remarks on the general nature of endemic hæmaturia and its parasitic origin.

B. M—, a well-made young man, aged twenty years, and a native of Egypt. He was admitted into the hospital on June 2d, 1882, and gave the following history of his case:—When he was twelve years of age he began to feel pain in voiding his urine, and wetted the bed every night. Four years ago he observed a small quantity of blood passing with his urine, or soon after it, and always with some pain. Latterly he had passed water about seven or eight times a day. At night he invariably had incontinence of urine and unconsciously wetted the bed. His strength was fair, but he was not able to sustain much or long-continued physical exertion. On his admission there was only a slight trace of anæmia, and with the exception of his urinary trouble he complained of nothing else. During his stay in the hospital the urine

was examined frequently, often daily, and with the blood, ova and free embryos of the bilharzia were at first always and plentifully found. In other respects the urine was not much changed from the normal state. Soon after his admission he was prescribed large doses of quinine, taking the first day sixty grains, and forty grains on each subsequent day for five days. But there was no change in any of the symptoms, and the blood passed was as full of ova and living embryos as before.

On June 14th I ordered a teaspoonful of oil of turpentine with a little milk three times a day, and this treatment was continued to July 8th. The blood was examined almost daily, and I was gratified to observe that in a few days it presented only broken ova and what appeared to be the debris of dead embryos. On the 25th the blood ceased, the nocturnal incontinence of urine stopped, the strangury was less, and the calls for micturition were diminished.

On July 8th he seemed to be perfectly cured. There was no blood, no ova in the urine, no strangury, and no incontinence, but there was still abnormal frequency of voiding his urine. At this date the oil of turpentine was stopped. He had taken it for a little more than three weeks. He was retained another week in the hospital for further observation, and was dismissed on the 13th. I saw him again about six weeks afterwards, and he reported himself perfectly well, with the exception of a slight pain in passing his water. I examined his urine and found it quite normal.

Remarks.—Though endemic hæmaturia has been long recognized as a distinct variety of bloody urine, its true nature and connection with the parasite was discovered in 1851 by Bilharz, a professor of anatomy in the Egyptian Medical School, who, with Griesinger, found the worm in the portal, mesenteric, and vesical veins, thus accounting for the presence of its ova in the urine. Dr. John Harley and others saw and described a number of cases from the Cape of Good Hope; and Dr. William Roberts says that the disease has been identified in the Mauritius and Brazil. To this geographical distribution I can add Syria, at least the town of Jaffa, from which place I have seen one unmistakable case, and have heard of others there; but this is the only Syrian case I met, though I have carefully watched for the disease. Bilharz and Griesinger found the parasite in 117 cases of autopsy out of 363; and they believed that probably more than half of the native inhabitants of Egypt were victims of this disease. Sonsino found it in thirty cases out of fifty-four; and he believes that nearly all the natives of Egypt have it. The symptoms of the disease are few and simple, but well marked. The patient complains of passing a small quantity of blood, varying from a few drops to a teaspoonful, just at the end of making water, with a little pain, which continues for a short time afterwards. The frequency of micturition varies from half a dozen times to a dozen. There is always more or less anæmia and a sense of weakness after any ordinary exertion. The quantity and specific gravity of the urine are natural, but there is always blood, more or less of albumen, and an abnormal deposit of mucus. In bad cases the reaction is alkaline, and the sediment shows a number of crystals of triple phosphates, indicating some degree of chronic cystitis, for which the disease may be easily mistaken. The chief point of interest in examining the urine is the ova of the bilharzia, which are found in large numbers entangled in the clots, though they may be often seen free among the blood corpuscles. They may be detected by a low power, and can be afterwards examined with one moderately high. They

are about 1-170th of an inch long, quite ovoid in form, with a spike at one extremity, and once seen cannot be easily forgotten. When the ovum is carefully examined with a magnifying power of 250 or 300 diameters, the embryo is seen within it, having a distinct border of its own lying close to the egg-shell, except at the two extremities. In some of the ova, which appear to be in a more advanced state of maturity, but not in size, the embryo may be seen to expand and retract itself, probably in a fluid which lies between it and the egg-shell. Dr. Harley hatched the eggs by immersing them in water. A more expeditious way is to crush the egg and liberate the embryo by gently pressing the two glasses. This can be done while the eye watches the process from above, and it is interesting to see the egg broken and the living embryo emerging from the shell, and its cilia put at once into vigorous motion. Not unfrequently free embryos may be seen with their broken shells among the blood-cells, occasionally, in very fresh specimens, racing across the field with incredible velocity. The form of the embryo is also ovoid, not much larger than the egg, having a somewhat pointed extremity, which appears to be the head or mouth; and projecting from its sides from one end to the other are innumerable fine cilia, which appear to be always in motion, though the animalcule does not change its relative position. It is supposed that the embryo must undergo more than one transitional stage before it assumes its ultimate shape of the adult worm. The worm, which never comes out with the urine, is described by Bilharz as a filiform body measuring from three to four lines in length. The male is thicker than the female, and has a long canal into which the female is received during copulation. It inhabits the portal vein and its branches, and the vesical veins, and can be seen only after death in post-mortem examinations. Nothing definite is known of the diseases to which this parasite gives rise, except the hæmaturia above described. The mucous membrane of the intestines is said to be affected, occasioning dysenteric symptoms, and I have been told lately by a medical man from Egypt that in such cases he has sometimes brought down with the fingers from the rectum nodules which were attached to the mucous membrane and which swarmed with ova. He has assured me also that the spine of these ova was lateral while that of the urinary ova was terminal. If this should be so, it would account for the statement of Bilharz and Griesinger as to some of the ova having lateral and others terminal spines, which has appeared strange to those who have, like myself, studied only the hæmaturic form. All seem to be agreed that the source of the parasite is infected and unfiltered water; and Sonsino adduces in support of this opinion the fact that Europeans and well-to-do natives never use the water of the Nile unfiltered, and are therefore exempt from the disease, while the lower classes use the water as it comes from the river and suffer accordingly. But I am not aware that anyone has seen the animalcule in infected waters. As a prophylactic measure it is suggested by Harley and Sonsino that drinking water should be conveyed in covered channels to prevent contamination by the excreta of persons infected with the parasite, that it should always be filtered, and that vegetables and fruits should be washed with filtered water before use. How the entozoon penetrates the bloodvessels and finds its natural habitat there is still a mystery. The size of the adult worm and of its ova and embryos precludes the idea that they can be carried through the capillaries or even through the smallest arteries and veins. In one of my cases I once opened a vein in the arm, but

found no traces of the parasite in the blood. If the ovum or embryo be the starting-point, it is difficult to understand how they can enter through any part of the absorbent system into the blood-vessels. Dr. Harley supposes that during bathing the leech-like animal may lay its eggs through the skin into some superficial vein, or more likely find its way into the bladder through the urethra.

The case recorded above is the only one in which I succeeded in obtaining apparently a perfect cure. The drug used was oil of turpentine, given in teaspoonful doses three times a day, and continued for about three weeks. I had employed in my previous cases every method which I had read of, or which suggested itself to my mind, but without the slightest effect on the disease as such. When strong tonic medicines were given the general strength may have been slightly benefited; but the examination of the urine revealed in each case the persistence of the parasite. Among other things I tried ten-minim doses of oil of turpentine, with the same quantity of extract of male fern, and carbo-lic acid, by the mouth and hypodermically, for some weeks, until the system was thoroughly saturated with it, and the urine became smoky. Injections with one-scruple doses of iodide of potassium into the bladder, as recommended by Dr. Harley, I never employed as far as I could wish, and the result was abortive. But in the case he mentioned it does not appear that the success was all that could be desired, for "the patient still passed a few eggs . . . and the ova were in a more lively condition."

P.S.—I should have preferred to delay this communication until I might have had another case for testing again the efficiency of the oil of turpentine; but in the present circumstances, when the disease is attracting so much attention, I thought it my duty to publish the only case of cure by medicinal treatment, so far as I know, and to leave to others, who are now seeing the disease, the opportunity of repeating the use of this drug, and finding out whether we have in it a real specific for endemic hæmaturia.

Beirut, Syria.

THE CLINICAL CLASSIFICATION OF BACKWARD DISPLACEMENTS OF THE UTERUS.¹

By G. ERNEST HERMAN, M.B. and M.R.C.P. Lond.,

Assistant Obstetric Physician to the London Hospital, Physician to the Royal Maternity Charity, etc.

It is a truism in medicine that for treatment to be successful diagnosis must be accurate. The backward displacements of the uterus, retroversion and retroflexion, are met with sometimes without symptoms, sometimes with symptoms; and in the latter case the symptoms, in different instances, differ widely in kind as well as severity. In some cases the symptoms are removed with striking rapidity and completeness by mechanical treatment, while in others the same treatment entirely fails to relieve. Clearly, therefore, all cases of backward displacement of the uterus are not alike; and before we can treat them with any approach to certainty of result, we must be able to make a diagnosis between those cases which require a particular treatment and those which do not; in other words, they must be classified.

The classification at present most in favor depends upon the shape of the uterus: whether it is bent or not; the sharpness of the bending; the greater or less difficulty of straightening it or keeping it straight. Such a classification of course

implies that bending is the important feature of the cases to be classified. I believe that bending of the uterus *per se*, as a rule, an unimportant condition. I have set forth the reasons which induce me to take that view, so far as dysmenorrhœa is concerned, in papers communicated to the Obstetrical Society of London; and therefore I need not here again defend it. I will only make these assertions: that there are many cases in which symptoms associated with retroflexion will entirely disappear, without any appreciable alteration in the shape of the uterus having taking place; and that there are many others in which mechanical treatment, perfectly successful so far as removing the flexion is concerned, fails to remove the patient's symptoms. Cases such as these are not exceptional, but quite common. Of course there are others in which the reverse is the case. But the existence of the former class of cases is enough to show that a classification based merely on the shape of the uterus is not an adequate one, not one which helps in the treatment of backward displacements of the uterus.

To make clear the principles upon which I think that distinctions should be drawn between different cases of backward displacement, I would ask attention to the circumstances in which such displacements occur, and the condition upon which, in my opinion, the symptoms connected with them depend.

The essential abnormal condition which produces these displacements is yielding of the pelvic floor—that is to say, the muscles, fascia, fat, and cellular tissue, which form, as Dr. D. B. Hart has pointed out, a compact layer closing the abdominal cavity below. I see no reason for attributing them to an isolated alteration in any single structure; for it has been shown by experiment² that different component parts of the pelvic floor may be separately divided without producing descent or displacement of the uterus. When slight yielding of the pelvic floor takes place, one of the first results is that the mobility of the uterus is increased, and that this organ slightly sinks. The greater mobility of the uterus which the loosening of its supports obviously involves allows it to fall either forwards or backwards. If it were rigid, a falling forwards or backwards of its body would be accompanied with a relative elevation of its cervix in the contrary direction, seeing that the uterus is most firmly fixed at about the level of the os internum. Often this is what takes place, and then we have anteversion or retroversion, as the case may be. But sometimes, instead of altering its position in the manner described, the uterus bends, the body thus sinking without much change in the position of the cervix. Retroversion and retroflexion are thus results of a slight degree of prolapse. They are often, indeed, valuable indications of a slight yielding of the pelvic floor. There are cases in which the uterus, while the patient is in the ordinary obstetric position, is not measurably lower in the pelvis than natural, and yet we find symptoms. Did we look to the amount of descent of the uterus appreciable by the medical man as the indication for mechanical treatment, we should detect no necessity for it; but the version or flexion of the uterus reveals to us the altered condition of the uterine supports.

This, then, is the first point to which I would ask attention; that retroversion and retroflexion, when pathological, are alike results of slight yielding of the pelvic floor. Without such yielding they cause no symptoms. Their presence with symptoms is an indication of a degree of prolapse

¹ Read before the Hunterian Society.

² Savage: *Surgery of the Female Pelvic Organs*, 1870, Pl. xi. Hohl (quoted by Aran): *Maladies de l'Uterus*, p. 98c.

which may be too slight to be detected in the ordinary obstetric position, except by the alteration in the inclination and shape of the uterus.

The next thing to be borne in mind is that the most common cause of yielding of the pelvic floor is parturition and its effects. After delivery the pelvic floor should return practically to its condition before the pregnancy. But this is not always the case. From the injuries to the parts which attend childbearing, and from disturbances in the process of involution, some loss of tone in the pelvic floor frequently results. Hence we find prolapse, retroversion, and retroflexion, chiefly in women who have had children, and comparatively seldom in virgins. But parturition also brings with it an increased liability to many pelvic disorders: metritis, perimetritis, ovaritis, etc. These conditions are thus very commonly associated with backward displacement of the womb, simply because they are prone to occur in the same class of patients.

Anteversion and retroversion resemble one another in being alike results of slight prolapse. But the consequences of these displacements differ, for the reason that behind the uterus there is occasionally an anatomical disposition of parts to which there is nothing analogous in front of it. There are two folds of peritoneum, containing some muscular and fibrous tissue, running back from the neck of the uterus to the sacrum—the utero-sacral ligaments. These bands vary very much. Commonly they are small, wide apart, and loose; they may even not exist at all as visible folds of peritoneum. Sometimes they are so strong, tense, and close together that Douglas's pouch is a sac with a distinct and narrow neck. When this disposition of parts is present and the uterus becomes displaced backwards, its body may, by the intra-abdominal pressure acting on its anterior surface, be forced down into Douglas's pouch, against the margins of which the veins running in the broad ligaments, and returning the blood from the body of the uterus, will then be pressed. The return of blood from the uterus may thus be obstructed, and congestion of that organ be the consequence. The body of the uterus may even, there is reason to believe, be so far pushed down as to become grasped by the utero-sacral ligaments, and incarcerated in Douglas's pouch. It is rare to find these ligaments so tense and so close together as to be capable of grasping the body by the uterus. But it is not uncommon to find one or both of them quite strong enough to be capable of exerting pressure on the veins of the broad ligaments when the body of the uterus is pressed down between them.

The utero-sacral ligaments have another effect besides this. When strong and tense they tend to restrict movement of the neck of the uterus in a forward direction. Hence when, this condition of parts being present, the body of the uterus becomes displaced backwards, the utero-sacral ligaments prevent the cervix from moving upwards and forwards. The womb therefore bends, and retroflexion is the result, instead of retroversion, which would be the kind of displacement produced if the cervix were free to move.

I would now ask permission to briefly repeat the important points in what I have been saying:—

1. Backward displacement of the uterus, when pathological, is a result and indication of slight yielding of the pelvic floor.
2. It is prone to occur in the class of patients who are most liable to inflammatory and other diseases of the pelvic organs.
3. The disposition of parts behind the uterus is sometimes such that when the uterus falls back-

wards, the veins which return the blood from it are pressed on, the return of blood is impeded, and the uterus becomes congested.

On this view of their pathology I would classify backward displacements as follows:—

1. Those which cause no symptoms of any kind.
2. Those in which the displacement (including under that term the totality of the conditions which produce it) is the only morbid condition present, and there is no congestion, the symptoms being those of prolapse only.
3. Those in which there is not only descent, but congestion of the uterus.
4. Those in which the displacement is complicated by other conditions, which may or may not be aggravated by it.

Upon each of these classes I would now offer some further remarks:—

1. It is difficult to get at a correct estimate, at least in this country, of the frequency with which retroversion and retroflexion occur without any symptoms; and it is not of great practical importance. Circumstances every now and then make it our duty to examine the pelvic organs, although the patient has never complained of any functional disturbance referable to them. No one can have made many such examinations without occasionally finding the uterus displaced backwards; and from the few such patients whom one is required to examine, one may infer as to the many whom one does not examine that such displacements occur also in them. Further, retroversions and retroflexions have been found post mortem in patients who were known not to have any uterine symptoms during life. But the most important piece of evidence, from the large numbers of which it consists, is that furnished by Vedeler.³ This physician, who practices in Christiania, examined 414 healthy virgins, and found the uterus retroverted in 45 of them, or 11 per cent., and retroflexed in 13, or 3 per cent. He also examined 506 healthy nulliparae, and found retroversion present in 47, or 9 per cent., and retroflexion in 17, or 3 per cent. (I have myself examined 111 nulliparae who sought advice not for uterine symptoms, but for local contagious disorders, and I found retroversion twice present and retroflexion once.) Vedeler also examined 584 healthy women, each of whom had had one or more children. Among these he found 57 retroversions, or 10 per cent., and 69 retroflexions, or 12 per cent. In all, out of 1,504 healthy women, Vedeler found the uterus displaced backwards in 248, or 16·49 per cent. Out of 1,158 women who were suffering from uterine symptoms, he found similar displacements present in 259, or 22·37 per cent. Other writers have published statistics showing the frequency of retroversion and retroflexion in patients not selected by their seeking treatment for uterine disease, as well as in fetuses and children; but none have investigated such large numbers, or differentiated so carefully between the different classes of patients, as Vedeler. As evidence of his accuracy, I may compare one of his statistical statements with a similar one compiled from his own experience, by Dr. Graily Hewitt.⁴ This latter author, out of 1,205 women suffering from uterine symptoms and examined by him, found retroflexion in 112, or 9·3 per cent. Vedeler, out of 1,106 patients suffering from uterine disease, virgins being excluded, found retroflexion in 112, or 10·1 per cent. As retroflexion is not common in virgins, it is possible that if the few virgins probably included in Dr. Hewitt's tabular statement were subtracted

³ Archiv. für Gynäkologie, Band xix., S. 294.

⁴ Diseases of Woman, third edition, 1872, p. 5.

from it, as they have been from Vedeler's, the result might be to make the percentage of retroflexions almost the same.

It is necessary, in classifying the backward displacements of the uterus, to recognize the frequent occurrence of these cases—viz., those without symptoms; because in practice it is essential that we should always bear in mind that as retroversion or retroflexion may exist in a healthy woman without causing symptoms, so either of these displacements may be present along with functional derangement, which it has no share whatever in producing or modifying.

(To be concluded.)

EUCALYPTUS ROSTRATA AS A REMEDY FOR DIARRHŒA.

By T. J. HUDSON, M.B., L.R.C.P. Lond.,

Resident Medical Officer, Leeds Public Dispensary.

I AM induced to bring the above drug more prominently before the notice of the profession owing to the very marked success its administration has met with in my hands in over two hundred cases of various forms of diarrhœa during the past summer. Not that it is by any means a new remedy, though noticed cursorily in the text-books. *Eucalyptus rostrata* (Australian red gum) was first brought into Europe by Sir Ranald Martin, and occurs as imported in dark-red hardish masses, its essential principle being tannic acid. It is supplied in a pure form by Messrs. Harvey & Reynolds, of Leeds. The preparations found most useful have been a concentrated decoction (strength 1 in 20), and a dilute (strength 1 in 40) made by boiling the powdered gum in distilled water for ten minutes, and filtering while hot, and a syrup (strength 1 in 3). For a moderately severe attack in the adult I commence with half an ounce of the dilute decoction every two hours. If after four doses no improvement results, the same quantity should be given every hour for four times, and if still little effect is apparent, I order half an ounce of the strong decoction every two or three hours. In the vast majority of suitable cases an abatement of the attack now occurs, going on rapidly to a cure, when the same dose should be ordered every five or six hours, only gradually discontinuing the remedy. In an acute case it is best to commence with the strong decoction at the first; half an ounce every two hours, and at times every hour, increasing the time as above. The syrup may be given to children in doses of five to twenty or more drops three or four times a day, but, mindful of the tendency of sugar or mucilage to run into fermentation, seldom prescribe it, preferring small doses of the dilute decoction (thirty to sixty drops) guarded with spirits of camphor or some simple carminative every few hours, pushing it if needful. In many of the worst cases occurring in children, when all other remedies have failed, this alone has effectually stopped the alvine flux. The forms of diarrhœa alone benefited by this drug are as follows—viz.:

1. That arising from want of proper assimilation, the unaltered food causing irritation, chiefly of use after this or other harmful substance has been removed from the alimentary canal.
2. The bilious.
3. The congestive, an inflammatory state of mucous membrane existing, most useful in the latest stages, that the result of sewer gas also coming under this head.
4. Summer or sporadic cholera.
5. That the result of amyloid degeneration of the intestines, usually the small.
6. The

chronic or white flux; of great service in this variety.

The above applies equally to children. In cases of intermittent diarrhœa, the patient having an attack every two or three days for some time, while well in the interval, the drug is very effectual, given as above twice or thrice daily. It is also of service in those cases which, when first seen, present great depression, where the offending cause must be allowed to take its course, and where opium is contra-indicated. The good results obtained are not simply owing to the tannic acid contained therein, as many cases unaffected by the latter are soon cured by the red gum, partly, no doubt, owing to the far less irritant properties of the decoction. It is contra-indicated where there exists much acidity or flatulence, and if the griping pains are very severe a few drops of laudanum may at first be added with advantage, but omitted so soon as this symptom is in abeyance. It adheres firmly to mucous surfaces, diminishing their secretion, coagulating the albumen, the uncombined portion serving to constrict and contract the vessels of the gut, and to give the latter tone.

As tannic acid diminishes the solvent power of gastric juice, the gum should not be given too near food. Its taste is rarely objected to, and can be improved by the addition of spirit of chloroform. Lastly, its cheapness is a desideratum, more especially in dispensary and hospital practice.

Leeds.

FATAL CASE OF LARYNGISMUS STRIDULUS.

By JOHN MCMUNN, L.R.C.P., Ed., L.R.C.S.I.,

Late Demonstrator of Anatomy, Carmichael College, Dublin.

On May 5th, 1882, a woman sought advice for her little daughter, aged one year and nine months. The general health of the patient was good, but at certain times she lost her breath and had to struggle hard to regain it. There were three previous children, all of whom had died in infancy. The duration of disease in the present instance was three weeks; such was the mother's story. The child looked healthy, voice and respiration were normal; the lower gum was swollen and tense over the sites of the temporary molars. Finding here a probable exciting cause of what I believed to be laryngismus stridulus, I determined to lance the gums. As the knife grated on the subjacent tooth the child commenced to cry violently, but at the expiration of one long loud cry it became silent. Breathing was suspended. After the lapse of a couple of seconds a struggle for breath ensued, the face assumed a frightened look, the mouth was widely opened, the trunk and limbs were stiffened, the toes and fingers worked, while the inspiratory muscles were thrown into violent contraction, and signs of asphyxia rapidly developed; the face grew livid, drops of sweat stood on the forehead, the pulse grew feeble and small, while with widely dilated pupils she turned and suffused eyeballs seemed to start from their orbits. Violent inspiratory efforts culminated in general convulsions. Soon all was still, the pulse vanished from the wrist, impulse and sound ceased over the heart, and general muscular reaction took the place of contraction.

Treatment.—The child was shaken, its face mopped with a wet handkerchief, its back and stomach slapped with the wet hand, attempts to excite vomiting were made, the tongue was drawn forwards, and the vapor of chloroform blown down the throat from the palm of the hand, when muscular relaxation took place; artificial respiration was carried out for some time, while

endeavors were made to excite anew the heart's action. Tracheotomy was proposed early, but no reasonings would induce the mother to give her consent.

Remarks.—The tongue of a child is fitted to the arch of the palate; it breathes through its nose; in crying the tongue is flattened, depressed, and drawn backwards. Laryngeal obstruction took place after a violent expiration, or at the commencement of an inspiration. Sudden falling of the epiglottis would be thus easily induced, this would induce spasm in the irritable muscles which guard the entrance of the wind-pipe, while further inspiratory efforts would tend to perpetuate obstruction, especially in the yielding larynx of a child.

Park-lane-terrace, W.

THREE CASES OF DEPRESSED FRACTURE OF THE SKULL, IN WHICH THE TREPHINE WAS SUCCESSFULLY APPLIED.

By H. BLANC, M.D.,

Professor of Clinical Surgery, Medical College, Bombay.

CASE 1. Depressed Fracture of the Skull; Slight Concussion of the Brain; Localized Inflammation of the Brain and its Membranes; Progressive Paralysis of the Face; Application of the Trephine; Recovery.—Appa Nartha, a Syce, aged thirty, a Hindoo of the Maratha caste, was admitted into the clinical surgical wards of the Jamsetjee Jejeebhoy Hospital on December 15th, 1880, suffering from a fracture of the skull. It appears that the horse Appa was leading suddenly reared and struck him on the forehead with its hoof. The patient fell to the ground insensible, and remained in that condition for a short time. Considerable hæmorrhage is said to have taken place. After a while, when he had recovered consciousness, he was unable to walk, even when assisted; he felt confused, his sight was dim, he did not recognize his friends for a time, and he had entirely forgotten how the accident occurred.

On admission, two hours after the accident, his condition was as follows. The face was pale and anxious; the pupils slightly dilated; the skin was hot and dry; the pulse slow (60), regular; he was conscious, and answered questions rationally; he complained only of feeling giddy and great weakness. On the forehead there was a contused wound, beginning just above the left frontal eminence, and running obliquely downwards towards the right side. The bone was exposed and fractured; a depressed fragment being distinctly felt with the probe; the parts around were swollen and painful; the right upper eyelid was ecchymosed. He progressed favorably for the following six days, but on the morning of the seventh day (Dec. 22nd) he complained for the first time of pain in the head. His sleep during the preceding night had been disturbed. There was some dyspnoea present, with increased frequency of respiration, and at the base of the right lung some dullness on percussion and increased vocal resonance were detected. Temperature 100°; pulse 60. The wound was dry-looking and of a dusky color. The following day he was better. The dullness at the base of the right lung had given way to treatment.—Dec. 26th: The pain in the head has been increasing gradually, and is now very severe; for the first time this morning some ptosis of the left eyelid is noticed. The breathing is shallow and hurried, although no physical sign of disease of the lung can be detected. Temperature normal; pulse 60, equal, somewhat compressible. On Dec. 27th the

attendant reported that the patient had passed a very bad night. The left angle of the mouth was depressed, and there was marked flattening of the whole of left side of the face. The wound on the forehead looked unhealthy, discharging sanious pus. Temperature normal; pulse 60. The progress of the case being decidedly unfavorable and localized, inflammation having been diagnosed, I decided on applying the trephine and removing the depressed fragments. The patient being placed under chloroform, a crucial incision was made, and the flaps, which included the pericranium, were dissected back. A depressed fracture was then found situated at the line of union of the frontal bones, but involving more the right bone. The fracture measured half an inch in breadth and one inch in length. All bleeding having ceased, and the parts having been thoroughly cleaned, a small trephine was applied, resting partly on the healthy and partly on the fractured bone. A portion of the bone having been thus removed, the depressed fracture was found to consist of several fragments which were easily removed, but around the fracture several detached fragments were also found, these latter belonging to the inner table of the bone, and some of them had penetrated through the dura mater into the brain. All of these were removed. A careful examination was then made to ascertain that no pieces had been left, when a little above the upper angle of the fracture a large fragment about half an inch in length was detected penetrating into the longitudinal sinus. It was very carefully removed; nevertheless a terrible gush of blood followed. I at once introduced my index finger into the wound and placed it on the spot whence the blood was flowing, and did not remove it until the hæmorrhage had entirely ceased. The parts were then cleaned and the flaps brought together by sutures, a fine drainage-tube having been previously introduced. The wound was dressed antiseptically. On the following morning (Dec. 28th) a great improvement was found to have taken place in the case. The temperature was normal; the pulse 72, of fair volume and regular; the respiration regular, 22; the ptosis of the left eye was much less marked, and the paralysis of the face had disappeared. He appeared cheerful, and answered questions rationally; he had quite lost the pain in his head.

For a while he progressed very favorably, but on Jan. 9th, 1881, he complained of difficulty in swallowing; there was some rigidity in the muscles of the jaw and neck; he vomited several times during the day; his tongue was foul at the base and red at the tip; his look vacant and stupid, and he did not answer questions readily; there was some return of ptosis of the left eyelid. He complained of no pain, and the wound looked healthy. On the 11th his condition was somewhat worse, and during the night he had an epileptiform convulsion. On the 12th he appeared somewhat better at the morning visit, but in the afternoon his condition became very critical; he was comatose; breathing hurried; pulse thready, 118; temperature 102.4°. During the following day (January 13th) he seemed several times on the point of death. Incontinence of feces and of urine; in deep coma, from which he could hardly be roused; the pulse at times imperceptible. On the 14th some slight improvement, but still very bad. On the 15th the improvement was more marked; he was again conscious; pupils still dilated, but less so; he could open his mouth better. Vomiting, which had been more or less persistent since the 9th inst., now ceased. Pulse 108, more full and regular; temperature 98.8°. The wound on the forehead, which had nearly healed, was found to be raised and pulsating, and the dressing was cov-

ared with a considerable amount of healthy pus. On the 20th he had made great progress towards recovery; the ptosis of the left eyelid had again disappeared. Temperature normal; pulse 86. He was quite conscious; answered questions rationally, slept at night, and asked for more food. Day by day he gradually improved, gained strength and flesh. His nights were good, and he seemed to enjoy his food; he was in good spirits and cheerful. A small pulsating tumour that had formed at the seat of the injury gradually increased in size, distending and partially separating the recently united skin flaps.

On the 1st of March the hernia cerebri was smaller, the granulation on its surface had healed, but it was still the seat of marked pulsations. He was soon able to take exercise about the wards and verandahs. By the 20th of March the wound on the forehead had partially cicatrized, and pulsations were no longer visible. He was discharged perfectly well on the 1st of April.

Some weeks ago I made inquiries regarding him, as I wanted to see him. His brother called at the hospital and told me that our patient had gone to his village on leaving the hospital, where he was still residing in the enjoyment of good health. He complains only of not being able to carry burdens on his head as he had formerly been able to do.

CASE 2. Depressed Fracture of the Skull; Compression of the Brain on its Convex Surface; Partial Paralysis and Contractions; Application of the Trephine; Recovery.—Pourbai Souter, a Mussulman woman of the Khoja caste, aged twenty-three, was admitted into the clinical and surgical wards of the Jamsetjee Jejeebhoy Hospital on Dec. 15th, 1881, suffering from a depressed fracture of the skull, caused by a box falling on her head from the third story of a house as she was walking in the street. She was taken to the hospital immediately after the accident. On admission her condition was the following:—There was a lacerated wound, some two inches in length, situated on the right parietal bone, near its centre, and extending backwards towards the occipital bone. The bone was fractured in the same direction as the external wound. The pupils were dilated, the left more than the right. Pulse 102; respiration 24; temperature 98°. There was no loss of consciousness, and no paralysis; but she was somewhat hysterical, and still under the influence of shock.

On the following day there was slight reaction. The temperature rose to 101.4°, and the pulse to 110. She was somewhat restless and delirious. There was retention of urine and costipation. On the 18th her condition was much the same, but some paralysis of the left lower extremity was noticed. On the 20th she experienced a rather severe epileptiform convulsion. On the 21st she was somewhat delirious, and during the night had another severe epileptiform fit. When conscious she complained of a severe pain in the head. There was increased paralysis of the left lower extremity, and some loss of power in the left arm. On Jan. 11th her condition was still worse, the loss of power in the lower extremity was more marked, and for the first time attended by muscular contraction. The arm was quite powerless. During the night she was very excited, but at the morning visit she was drowsy and listless.

In presence of the progressive and increasing paralysis of the left arm and leg, to which contracture was now superadded, the application of a trephine to the fractured bone was decided upon, and the patient being placed under the influence of chloroform, a crucial incision was made over the scalp wound. The flaps having been dissected, a small trephine was applied partly on the healthy and partly on the fractured bone, and on remov-

ing the circle of trephined bone a large fragment was found to have been pushed and firmly wedged beneath the sound parietal bone. This piece was removed by forceps. The dura mater at the spot appeared rough and congested, but it was not lacerated. The wound was united by suture, a fine drainage-tube being introduced. The wound was dressed antiseptically.

Jan. 12th.—The patient passed a good night. Moderate reaction present; pulse 104, temperature 101°. All symptoms of paralysis have entirely disappeared; she is able to empty her bladder without assistance. During the next forty-eight hours moderate reaction persisted, and she suffered also from chloroform vomiting; otherwise progress was most favorable. On the 18th the report of the case is the following: Temperature normal, pulse 76, of good volume; bowels regular, sleeps well, and asks for food. She can move her arm and leg freely. The wound looks very healthy, and is uniting. The further progress of the case was steady and good. She gradually regained her strength, and she was soon able to walk about the wards and in the gardens. When she left, on Feb. 2nd, the wound on the scalp was firmly united, and she was altogether in perfect health.

CASE 3. Depressed Fracture of the Skull; Concussion of the Brain; Contusion and Laceration of the Meninges; Acute Meningitis; Application of the Trephine; Recovery.—Rookmee Etaba, a Hindoo girl aged twelve, was admitted in the clinical surgical wards of the Jamsetjee Jejeebhoy Hospital on March 31st, 1882, suffering from fracture of the skull and other contused wounds, the result of a fall. Of somewhat weak intellect, and subject to epileptic fits, she was standing on the summit of a steep hillock (Belvidere Hill, Mazagon) when she fell to the ground, seized with an epileptic fit. Under the influence of the fit she rolled along the steep and rough incline of the hillock, some sixty feet. She was picked up insensible and at once carried to the hospital. On admission her condition was as follows:—There is a lacerated wound situated above the left eyebrow, and which extends directly upwards and backwards for about one inch and a half; the bone is exposed, fractured, and depressed at the centre of the fracture. Some deep lacerated and contused wounds are found in the following positions. One over the left malar bone, one some three inches in length over the left side of the thorax, another over the left hip-joint, and many smaller abrasions and contusions are seen on different parts of the body. Both ankles are much swollen and tense. She is still unconscious: pulse 80, small; respiration shallow, 80. She now and then starts and moans, and frequently carries her hand to the wound on her head.—April 1st: She is drowsy, but can be roused somewhat. She is unable to answer questions put to her. Bladder distended; ten ounces of urine withdrawn by catheter; specific gravity 1016. Towards noon the temperature, which had been normal until then, began to rise and acute delirium set in. Pulse 114; respiration 32.

April 2nd.—She passed a very bad night; great restlessness and delirium. This morning temperature 104°; pulse 114; respiration 32. All day she remained in the same condition, the pulse losing strength and becoming more rapid. The prognosis being very unfavorable, an attempt to relieve her condition by applying the trephine was decided upon, and at 6 p.m. she was placed under the influence of chloroform. A crucial incision having been made at the seat of the fracture and the flaps dissected back, a small trephine was applied over the centre of the fracture. This having been removed, a few loose small fragments were found lying on the dura mater. One sharp-pointed frag-

ment had lacerated the membranes and wounded the brain. From around and beneath the fracture some clots of blood were removed. The dura mater at the seat of the injury was much injected and of a violet color. A slight oozing followed the removal of the penetrating fragment. The flaps were brought together by wire sutures, a small drainage-tube being introduced. The wound was dressed antiseptically.—3rd: Still delirious, but less violent than the day before; urine withdrawn by catheter. Temperature 102°; pulse 104. She became more excited towards evening, and the temperature rose slightly.—4th: Passed a pretty fair night, neither noisy nor restless; she is still unconscious; passes urine in bed. The right ankle is much swollen and painful. Temperature 103°; pulse 100; respiration 24. Towards evening the temperature fell to 100°. The following days she remained in about the same condition, at times quiet, at times noisy and violent. She took nourishment badly. An abscess formed near the right ankle-joint, and after it had been opened (April 9th) the temperature fell to normal.—17th: Passed a fair night; answers questions when pressed to do so; generally lies quiet or moans; no longer passes water in bed, but calls for the nurse; takes nourishment fairly well; the wound on the head discharges slightly. Temperature 99°. For a while she again became somewhat violent and restless at night; several abscesses formed at the seat of the contusions, and much of the uneasiness she experienced about that time was doubtless due to these inflammatory abscesses. In the beginning of May the improvement in her condition was more marked; she understood what was said to her, but was unwilling to answer, and when she did so it was in a cross, angry tone, as if annoyed at being disturbed; she now slept well at night, her bowels were regular, she took her food better, her temperature was generally normal; the pulse averaged about 80, and was weak and compressible; the wound on the forehead was nearly healed, a few drops of sero-purulent discharge alone soiling the dressing; all the other abscesses were completely healed.

May 14th.—She is in a fair way towards recovery; is able to sit up in bed, takes her food well, is gaining a little strength; she is sulky and cross generally, and is still unwilling to speak when questioned. According to her parents she is intellectually very much the same as she was previous to the accident. Discharged at her parents' request.

The first case is one of a depressed fracture of the frontal bone, attended by slight concussion of the brain. On the seventh day after the injury the individual, who until then was doing well, was suddenly seized with progressive facial paralysis, dyspnoea, etc. These symptoms (taking into consideration the date of their appearance) indicated localized inflammation of the brain due to the presence of depressed and penetrating fragments of bone acting as a foreign body. That this was the case was amply proved by the result of the operation. The relapse which followed a few days afterwards was due to the contused brain undergoing suppuration, and owing to a free exit having been made by the trephine, the abscess was evacuated externally, and rapid recovery ensued.

In the second case we have to deal with a well-marked instance of functional disturbance of the brain. There was compression of the brain on its convex surface (a piece of bone being firmly wedged in), but unaccompanied by symptoms of compression. The paralysis and contraction which afterwards developed were due to disturbed cerebral circulation, and to localized congestion,

rather than to inflammation. This is implied by the rapid improvement that followed the operation.

In the third case there was severe concussion of the brain, with laceration and contusion of the meninges. The very rapid and unfavorable progress of the case made the prognosis a most serious one. Nevertheless, after the penetrating fragments had been removed the further progress of the cerebral inflammation was considerably lessened.

Apart from their diagnostic value, I think that these cases will assist in rehabilitating the operation of trephining the skull in appropriate cases. These three individuals would, in all probability, have succumbed to cerebral inflammation had not operative surgery interfered on their behalf.

Bombay.

NOTES OF THREE ABDOMINAL CASES OF INTEREST.

By J. A. CAMPBELL, M.D., F.R.S.E.,
Medical Superintendent, Carlisle Asylum, Carlisle.

CASE 1.—M. C—, a female, aged at death fifty-four years, had been admitted into the Carlisle Asylum in the year 1862, and at that time was described as laboring under mania and being in weak bodily health. My knowledge of her included the latter fifteen of the twenty years she lived in this asylum. She labored under many delusions, talked much to herself, enjoyed good bodily health until shortly before her death, and was industrious and useful. From the many entries in her case I find that little or no ostensible change in mental or bodily state was noticed up to January, 1879, when she had an attack of vertigo, and for some days felt out of sorts. She, however, continued in her usual bodily state during 1880. In the latter half of 1881 she became thinner, her skin became yellower than it used to be. On more than one occasion she was examined, but no active disease or indication of organic disease could be found. It was noted, however, that she had a cancerous look.

On Jan. 22nd, 1882, the patient complained of feeling ill, but owing to her incoherent expressions it was impossible to get her to say more than that she felt ill. She vomited, her tongue was moist and clean, her temperature normal; pulse 78, small. An examination of the chest showed a normal condition of the thoracic viscera, and nothing abnormal could be detected as regards the abdominal organs; as there seemed a tendency to constipation of the bowels an enema of tepid water was administered, which produced two alvine evacuations. On the 23rd there was little change in the patient; she took food, but looked ill. On the 24th the morning temperature was 99°; pulse 96. She looked worse. Abdomen tympanitic and tender to the touch; no fluid in the abdominal cavity. Ordered half a grain of opium in a pill each hour. In the evening she complained of acute pain, referable to the region of the stomach, was sick, and retched much. A hot fomentation was applied and retained for some hours over the abdomen, but as relief from pain was not at once caused by hot application a subcutaneous injection of morphia was administered above the region of the stomach. Cessation both of pain and sickness immediately followed this treatment. Pain and sickness, however, recurred later in the day, but disappeared on a repetition of the injection. On the 25th the morning temperature was 98°; pulse 96. Tongue furred and dry, pulse small, tenderness over abdomen, but nothing abnormal

could otherwise be discovered. Decubitus on the back, with a tendency to draw up the legs. On the 26th the morning temperature was 97°; pulse 74. Tongue furred; during the night the bowels had been three times moved, feces normal in color but unformed. Abdomen tympanitic, tense, and tender. On the 27th the morning temperature was 97°; pulse 80. Was weaker and looked worse. Abdomen less tympanitic and tense; has taken a fair amount of liquid food. On the 28th she was worse, pulse more feeble, skin cold. On the 29th she became worse and died.

Autopsy, forty-two hours after death.—The body was thin, and the skin tinged yellow. The brain was examined, but no abnormalities detectable by the naked eye were observed. Chest: The lungs were slightly adherent to the parietes by old adhesions; the bases of the lungs posteriorly were passively congested, and the structure of the lungs, on section, was normal. Heart: Muscular substance fatty; valves competent. Abdomen: The liver was light-colored, friable, and fatty. Gall-bladder contained twelve small dark-colored calculi (a large biliary calculus was subsequently found in the small intestine). The spleen was dark and soft, and the kidneys congested; otherwise normal. There was evidence of peritonitis of the outer coat of the intestine, more especially of the large intestine. There was no fluid in the abdominal cavity, and the peritoneum lining the abdominal parietes was in a normal state. The intestine was taken out and examined; nothing unusual, except the already mentioned biliary calculus, was noted about the small intestine; but the large intestine, down to the sigmoid flexure, was much distended and contained flatus. There was a ring of hard cancer about an inch above the sigmoid flexure, which formed a constriction, only admitting one finger; and about three inches above this there was an ulcer, about the size of a penny, with irregular and indurated edges. There were no other abnormalities in the large intestine.

CASE 2.—J. M.—, a female, aged sixty years at death, was admitted in June, 1871, laboring under melancholia, and in very weak health; pale, thin, cachectic-looking, and to all appearances very aged for years. I always suspected internal cancer from her appearance. All forms of treatment to improve her bodily health and to increase her weight (which on admission was 106 lb., height 5 ft. 2 in., and which diminished to 88 lb. within the first ten months), proved unavailing. She resented the slightest interference, never spoke, but bit, struck, kicked, or scratched, if any attempt at examination was made. She had a habit of rubbing her hands, and did so so continuously that an abscess formed connected with the first finger of the right hand, and also another abscess connected with the fourth finger of the left hand. In spite of treatment disease of the cartilage and bone set in in both fingers, and they had to be removed. Healing took place extremely slowly, in fact for a long time little or no change seemed to take place in the severed tissues. On March 1st, 1882, it was noted that she was becoming gradually thinner and weaker, and on more than one occasion, but at considerable intervals previous to this date, she had had a loose stool followed by great pallor, faintness, and coldness. She resisted all attempts at examination with extreme viciousness. On several occasions she has been examined while being forcibly held. The result of these necessarily imperfect examinations may shortly be stated—viz., that percussion over the chest was clear, that some mucous râles were heard over both lungs, that the heart sounds were feeble but distinct, and that nothing abnormal was detected by percussion or touch; as regards abdomen, her

temperature was subnormal, her bowels were moved regularly, she took a fair amount of food, but she became gradually paler, thinner, more cachectic-looking if possible, and died on March 7th, 1882.

Autopsy, forty-nine hours after death.—The body was thin, and free from marks of injury. The brain was examined, but no marked lesions were noticed, and it is, therefore, unnecessary to enter into a detailed account of the appearances. The left lung was closely adherent by old adhesions to parietes, especially at apex; its upper lobe was congested, both lungs contained some deposit of grey tubercle at apex. The pericardium contained two ounces of fluid; the heart was yellowish in color, its muscular substance was fatty, its valves competent. Liver light colored and friable. Spleen and kidneys normal. Stomach and intestines removed and examined; both were found in a normal state, with the following exception. At the caput cæcum there was a thickening and appearance of tumour, as if the caput cæcum were crammed full of contents of a firm nature; on removing and laying it open the whole of the inner surface of the caput cæcum was found covered over with irregular masses of hard cancer, but the cavity of the viscus was patent, the external surface presenting a smooth and normal appearance.

CASE 3.—E. H.—, aged thirty-four at death, was admitted in November, 1866. She was entered as a congenital imbecile in weak health, unable to answer questions though able to speak a few words, was dirty in habits, ill-tempered, passionate, and at times violent. By dint of careful attention she improved in habits and conduct, and her bodily health improved. In 1873 she had an attack of excitement which lasted nearly six months, and during which, in spite of careful feeding, she lost weight. From this date till March, 1882, she remained in her usual mental condition. During the period of more than fifteen years that she had been an inmate of this asylum she had been free of physical ailment.—March 25th: Patient had taken food the day previously as well as usual, and seemed in her ordinary state of health when she went to bed. During the night her bowels were moved. The motion was reported as natural in color, size, shape, and consistence, by the night attendant. After this she was rather talkative, and appeared as if pained. As she looked ill she was kept in bed. She refused breakfast. I saw and examined her with all the care I could shortly after 9 A.M. There were no marks on the body. Temperature 97°; pulse 80, very weak. The tongue was slightly furred, with a tendency to dryness. The heart's sounds were feeble. There was comparative dullness over the left lung, both anteriorly and posteriorly, and respiration was harsh; but no crepitation, mucous râles, or other abnormal sounds heard. The abdomen was examined, and nothing abnormal was detected. There was no increase in size, and no abnormality noticed by touch or percussion; the patient exhibited no fear of being examined; no tenderness on pressure. The patient seemed to have a tendency to sickness, though she did not vomit. I was at a loss to know what was wrong, but thought it probable that she was going to have an attack of acute chest disease. I ordered a mustard poultice to be applied to the left side, and liquid nourishment to be given to the patient. At noon, while sitting up taking some beef-tea, which she was doing with avidity, she suddenly fell back in bed, and had a slight epileptiform convulsion, her eyes turning round. She became sick, vomited the beef-tea she had taken, passed urine in bed, and died in a state of collapse within forty minutes.

Autopsy, twenty-eight hours after death.—Body free

of marks; rigor mortis present; face and lips pale; pupils equal, rather dilated; thumbs inverted. Head: Brain examined, no abnormality noticed. Chest: Right lung free in cavity, very slightly congested; left lung very slightly adherent at apex by an old adhesion; left lung was slightly congested, principally posteriorly; structure of both lungs normal. Heart: Muscular substance normal, valves competent. Abdomen: There was a considerable amount of blood-tinged fluid in the abdominal cavity, and on the contents of the abdominal cavity being fully exposed, a large portion of the ileum and of the large intestine were seen to be quite black; there was, in fact, a twist of a large mass of intestine. Ligatures were applied to the lower ends of the duodenum and colon and the mass removed. Eight feet (measured) of the small intestine were found to be black and strangled, and a foot of the descending colon was similarly affected. The intestine, though black, was found strong and fresh on traction, showing recent strangulation. There was no ulceration of intestine, and no abnormality of parietal peritoneum. The liver, spleen, kidneys, uterus, and ovaries were normal; the stomach and urinary bladder empty.

Remarks.—I have endeavored to eliminate extraneous matter and to condense the account both of the cases and autopsies from the reports in my possession so as to save the reader from needless mental exertion. In an asylum containing from 400 to 450 patients, with an average death-rate of only 7 per cent. per annum, calculated on the average numbers resident, to have within two months three deaths from causes such as are narrated above is a remarkable coincidence. That abdominal cases are about the most obscure, the most uncertain, and the most difficult to deal satisfactorily with is almost an axiom. The difficulty in diagnosing and treating physical disease in the vast majority of the insane is as great as, and in many cases even greater than, in dealing with young children; no indication of the seat or nature of the malady can be communicated by the patient. In the three cases reported no aid of this sort was really available; in one, the first case, pain was complained of, but during most of the illness many vague complaints were made, and they were made only in a semi-coherent manner. In the second case active resistance to examination complicated matters; and in the third and last case real mental defect prevented the power of communicating symptoms. In the first two cases I suspected internal cancer from the general appearances, but was unable to localize it. In the first case, that of M. C., the yellowish tinge of the skin, the sickness, and pain in the region of the epigastrium might be, and probably were, the result of the gall-stone complication. The great prevalence of gall-stones in the insane has been noted in other asylums as well as in this. Considering the gravity of the intestinal lesion, it seems rather astonishing that signs of bowel complication should not have set in earlier, and have been of a more intense character. The unformed character of the stools was noted; but this means really nothing, for I have seen in a case of very narrow stricture of the large intestine large solid and firm faeces passed, which must have solidified and formed in the lower part of the gut. In the second case the position of the cancer and its not in any way affecting the outer surface of the caput cæcum are noteworthy points. I find that out of 589 deaths in this asylum (and the cause of death is not conjectured, but is ascertained by post-mortem examination) twenty-nine, or nearly 5 per cent., have been caused by cancer; of this number eleven have been due to cancer of the stomach or in-

testinal canal. I have not data to enable me to comment on the proportional death-rate in other similar institutions from this disease. Were a uniform system of recording, tabulating, and publishing the causes of death in asylums and hospitals in force, clearly stating where the result was ascertained by post-mortem examination, a comparison of such fatal diseases would help in forwarding our knowledge of their history and habitat. In the third and last case, the symptoms and post-mortem appearances clearly point to a very recent strangulation. I believe the effusion found in the abdominal cavity took place within three hours, between the time I examined her and her death. That the strangulation should have affected the parts it did seems strange to me. The largeness of the portion of intestines strangled undoubtedly caused the rapidity of death; death in this case really resulted from shock.

SALICYLATE OF SODA IN ACUTE ORCHITIS COMPLICATING GONORRHOEA.

By EDWARD HENDERSON, M.D., F.R.C.S. Edin.,
Municipal Surgeon, Shanghai.

THE marked and speedy relief of pain which follows the administration of salicylate of soda in rheumatic inflammation of the joints has been for some time past a matter of common clinical observation. The success which I have myself had with this drug in treating these affections led me in the autumn of 1880, while in charge of the Shanghai General Hospital, to give it a trial in a case of acute epididymitis occurring as a complication of gonorrhœa. Since then I have had but two satisfactory opportunities of repeating the experiment; I regard, however, the results obtained in these three cases as sufficiently good to warrant further trial of the remedy, and, indeed, entertain the hope of finding by more extended experience that we possess in salicylate of soda a drug which exercises something very like specific influence over the disease.

CASE 1 was admitted to the General Hospital on September 13th, 1880. The patient contracted gonorrhœa about three weeks previously. For a week the left testicle had been somewhat swollen and painful. On the 11th the swelling increased considerably, and the pain became severe and constant. On the 12th he suffered a good deal, and was unable to leave his bed; that night the pain prevented him from sleeping, and he had fever. On admission, at 10 A.M., his temperature was 102°. The left testicle was about four times larger than the right, and the scrotum covering it was red, being stretched and glossy in front, and somewhat œdematous below. There was great tenderness. The urethral discharge had disappeared. I thought the tunica vaginalis implicated, and regarded the case as probably a suitable one for treatment by puncture, as recommended by Mr. Smith and others. Salicylate of soda was ordered in twenty-grain doses hourly until the pain should be relieved. At 4.30 P.M. four doses had been taken—namely, at 11.10, 12.10, 1.10, and 4. He had sweated profusely, and the pain had greatly diminished. At 8 P.M. his temperature had fallen to 100°, and the medicine was ordered to be continued at intervals of four or six hours. He slept well that night without an opiate. On the following morning (the 14th) his temperature was 98.4°, and he felt quite easy while lying down. Pain had altogether left him on the 15th, and the urethral discharge returned on that day. There was no relapse.

CASE 2.—A police constable, seen by me for the

first time on the morning of April 8th, 1881. Patient contracted gonorrhoea about a fortnight before that date. One of his testicles had been swollen and painful for five days, but, until the morning of the 8th, he had been able to do patrol duty; being then no longer able to walk, he was compelled to go on the sick list as suffering from venereal disease. The inflammation was confined to one testicle, which was between two and three times larger than the other; it was hard and very tender. The scrotal skin was red, but not glossy. The body of the testicle was perhaps affected in this case along with the epididymis. There was apparently no discharge from the urethra. The patient's skin was hot to the touch, and his tongue was coated. He was ordered salicylate of soda in twenty-grain doses every two or three hours according to the effect produced. The testicle was to be suspended in hot water from time to time during the day. By evening six doses of the medicine had been taken, and the pain was greatly relieved. The pain diminished, he said, after the first dose, when he began to perspire. In the afternoon he sweated profusely. On the following morning (the 9th) he was quite easy when lying down, and could bear the testicle to be handled freely. On the 10th he declared that all pain had left him, and asked to resume duty. The testicle was then distinctly less swollen, though still enlarged and indurated. Convalescence was uninterrupted. The urethral discharge returned, but I have not noted the date of its reappearance.

CASE 3 was first seen on June 15th, 1882. The patient contracted gonorrhoea a month before that date. For about eight days the right testicle had been somewhat swollen and painful, and at the same time the urethral discharge began to diminish, and finally disappeared. On the 13th the inflammation seemed to be subsiding; but on the 14th the patient walked a good deal, and by the evening of that day the testicle was much more swollen than it had yet been, and the pain was severe and constant. On the morning of my visit he was forced to remain in bed. He said he had had an "awful" night from pain, and had been quite unable to sleep. His temperature was 101·8° F.; pulse 90; tongue clean and dry. His bowels were confined, one small hard motion on the morning of the 14th, and the same on the morning of my visit (15th). The inflamed testicle was at least four times larger than the other, hard, and very tender. The scrotal skin covering it was dull red, stretched and somewhat glossy in front. I ordered twenty grains of salicylate of soda every two hours, avoiding any other treatment, local or by aperients. The medicine was taken at 11.30 a.m., 1.30, 2.30, 4.30, and 7 p.m. After the second dose he had some ringing in the ears and began to perspire. After the third dose sweating was profuse (the weather was warm). At 4.30 p.m., after the fifth dose, the pain was relieved. At seven o'clock I saw him again; his temperature was then 101·6°, and his pulse 84; the pain was much less, and he could bear the testicle to be handled with tolerable freedom. On the following morning (16th) his temperature was 99·4°; pulse 88. He had taken two doses of the medicine during the night. He had slept well, and now complained only of slight pain confined to the upper part of the testicle. The testicle was much diminished in size, and fluctuation could be distinctly felt in front. His bowels were not moved till the evening of that day. Convalescence was uninterrupted and satisfactory.

In further trials of this plan of treatment I would advise that only acute cases be selected, the evidence of that condition being a distinct rise of temperature as ascertained by the thermometer.

The dose of the salt should be not less than twenty grains, and should be repeated hourly until at least three doses are taken; afterwards the same dose may be continued at longer intervals.

Shanghai.

ON SOME DEFORMITIES OF THE BODY INCIDENT TO THE PERIOD OF GIRLHOOD.

By CHAS. ROBERTS, F.R.C.S.,

Late Assistant-Surgeon to the Victoria Hospital for Sick Children, Etc.

I HOPE the time is not distant when a careful study of the living model of the child and the adult, and the whole period of the development of the one into the other, will form a part of the student's ordinary course of anatomy and physiology, as such knowledge is essential to the surgeon engaged in removing and preventing deformities of the body. Orthopaedic surgery as a specialty is a great evil both to the profession and the public. The specialist who concentrates all his attention on a narrow field of study and practice is tempted to exaggerate its importance, and to analyze and disintegrate his facts till he loses sight of their relation to, and their dependence on, each other; while, on the other hand, the general practitioner is disheartened and repelled by the apparent complication of the subject, and is induced to hand over to the specialist many cases which he is quite competent to treat, or, as is too often the case, to undervalue the importance or deny the existence of many deformities. How else can we explain the difference in practice between the fussy mechanical ingenuity with which many professed orthopaedists treat the slightest deformities of children—which, by the way, they often tell us are only visible to their specially trained eye, and are hidden from that of the family doctor—and the sangfroid of the general practitioner who meets the difficulties by the administration of a few doses of steel and quinine and rest in the recumbent position?

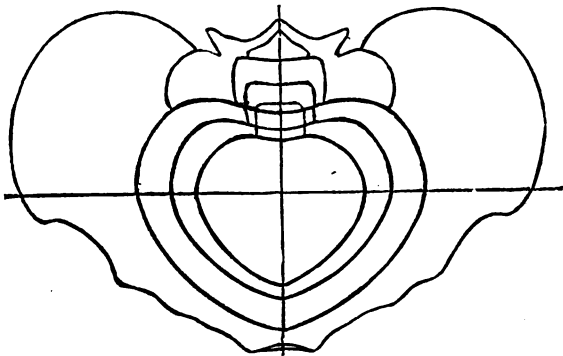

No deformity of a child's body gives rise to so much alarm to parents, or is the subject of greater diversity of treatment among medical men, as lateral curvature of the spine, and this is due, I believe, to an imperfect acquaintance with its origin. Specialists are accustomed to treat lateral curvature, knock-knee, and flat-foot as distinct deformities, while in truth they are all links in the chain of one deformity. Lateral curvature may arise in different ways, but in all cases it is due to the loss of the lateral balance of the body in the upright position, and is the result of an effort of nature to maintain the centre of gravity of the body and support the head and shoulders in the position which requires the least expenditure of muscular effort. The paralysis, wasting or loss of a limb, or the shortening of one of the legs by disease of joint, rickets, knock-knee, or flat-foot in growing children, will produce lateral curvature, and these are its chief if not its only causes. It is not a deformity arising from general debility, and I do not think it can be produced, as is often asserted, by an awkward sitting position, as in writing and other school occupations. The curvature of the spine which results from these causes is antero-posterior, or what is commonly called round-shoulder (non-carious). The tendency of debility, whether local or general, is to bring the body into the prone or recumbent position, and not to tilt it on one side.

Setting aside the cases of lateral curvature in children who have been affected with rickets, disease of joints, paralysis or loss of a limb in early

life, and which affect both sexes, and all ages equally, what may be called the idiopathic or acquired deformity is rarely found in children of either sex under the age of nine or ten years, and very rarely in boys above that age. It is, indeed, almost peculiar to girls verging on puberty, and is as often found in strong and healthy as in weak and delicately built girls, and most commonly in those who are too fat and heavy for their stature and age. It is a deformity which is less common among the laboring classes than among the rich and well-to-do, and is largely associated with a life of indolence and luxury.

A careful examination of the subject has satisfied me that this acquired lateral curvature in girls is due to the change in the position of the lower limbs resulting from the development of the pelvis from the infantile to the female type a year or two before the accession of puberty. Anyone who will examine the figures of young children below this age will find little differences between the two sexes. The legs of young girls are set on the body like those of boys, and, within the limits of their training and dress, they can run as well and as gracefully as boys; but as puberty approaches and the pelvis alters its shape, the heads of the femora are removed further from the centre of gravity, and at the same time become rotated forward by the widening of the pelvis, and especially of the outlet of the pelvis. The effect of these changes is to bring the knees closer together, and pro-

ducing girls. A little additional strain will convert it into knock-knee, and by throwing the weight of the body on the inner ankle, it will quickly break down the arch of the foot and produce flat-foot or complete eversion of one or both feet. It is here, indeed, that nearly all the mischief lies, for according to my experience ninety per cent. of the cases of lateral curvature of the spine in girls are associated with flat-foot. This deformity is exceedingly common among women, and a French *savant* recently quoted it as a proof of the physical inferiority of woman to man. To a slight extent flat-foot may exist in all women, as the position of the lower limbs after puberty would seem to produce it, and it may be nature's plan to promote what anthropologists call marriage by capture; but to a large extent, and in its worst forms, flat-foot is the result of civilization. Indeed, both the highly arched instep and the everted foot are peculiar to civilized peoples, and are absent from the lower races, especially those who go barefoot, and both conditions owe their existence to the wasting of the muscles which flex the toes and foot by the constant use of tight-fitting shoes. In India, where the native workman makes use of his toes with almost the same facility as his fingers, the instep is obliterated by the fleshy bellies of the abductor of the great toe and the short flexor of the toes, which stretch across the arch from their attachment to the heel bone. The wasting of these muscles is of little

The diagram shows the relation of the brim of the pelvis in the child, at puberty, and in the adult female, from measurements of pelves in the museum of the Royal College of Surgeons. The want of parallelism of the two inner pelvic curves shows that in the change from the infantile to the female type evolution takes place chiefly behind, and that the legs must be rotated forwards and inwards. The dimensions are:—Child: breadth 83 mm.; length 73; index 114. Young female: breadth 112 mm.; length 85; index 132. Adult female: breadth 143 mm.; length 108; index 132. The indices of the young female and the adult are the same, but the bones of the former are not united together.

duce the weak-kneed condition and the awkward running gait peculiar to women. This condition of the limbs is well seen in pictures and statues of the nude figure, and it is often exaggerated by the artist or sculptor, probably to give a more distinct idea of a woman's helplessness or modesty. The knee-cap in women looks straight forward, while in men it is turned a little outward; and in women the knees touch, or even overlap each other, while in men they are quite free. In running, a woman has to move the knees around each other, and to throw the feet out in a succession of small semicircles, which accounts for the peculiarity in her gait. This gait is not found in young girls before the onset of puberty, and is useful as a diagnostic sign of pelvic evolution long before the ordinary signs appear.

Although this weak-kneed condition is quite normal, it is a fruitful source of deformity in

importance to us who have no need to use our toes in detail; but it is far otherwise with the deep flexors of the foot and toes which are attached to the leg bones, and whose tendons pass under the ankle-joint and arch of the foot and form their chief support. It is, indeed, from the wasting or inaction of the deep flexor muscles, coupled with the turning out of the toes which fashion has imposed upon us, that the ankle and arch of the foot give way under the changed position of the limbs in girls at puberty, which I have described; and what is remarkable, and not easily explained, the deformity generally occurs only in one foot, or is greater in one than the other. In this way, however, the legs become of unequal length, and we have obliquity of the pelvis, and consequently, lateral curvature of the spine to correct the balance of the body, and bring the head and shoulders into the line of the centre of gravity. Flat-foot

also produces, or exaggerates, the natural disposition to knock-knee in girls, which, in its turn, adds to the inequality in the length of the two legs. Some observations recently made in America show that even in adults of both sexes the two legs are rarely of equal length, and there must be, therefore, slight lateral curvature in all persons, and it is probable that these natural curves become exaggerated, as in the development of round shoulder the large antero-posterior curves of the spine are exaggerated. It is to the wasting or non-development of the fleshy parts of the deep flexors of the toes or foot that Europeans owe the small ankle and the comparatively large calf of which they are so proud as distinguishing them from the lower races. It is a distinction, however, which is more than counterbalanced by the ugliness and inconvenience of flat-foot, to which it frequently gives rise. The ingenuity of an Edison could not devise a machine so favorable to the production of flat-foot as the tight-fitting, high-heeled, long-topped boot at present worn by girls. Not only does the rigidity of the front part cramp the action of the muscles, but the high heels place the foot at such an angle with the leg that the tendons are of least use in supporting the ankle-joint, and the long tops hamper the development of the muscles in the remainder of their course. The high heels, moreover, push the centre of gravity forward on the arch of the foot, and by propping up the heel gives greater leverage, and a greater space for the arch to fall when once it gives way. In the majority of cases the mischief would stop when the arch reached the level of the natural heel, but the heels of boots favor a still greater fall, which ends in eversion of the foot. It is difficult to understand how women submit to the discomfort of wearing high-heeled boots, or can be so cruel as to let their daughters wear them. It is true they give a fictitious height to the body, and disguise the slighter forms of flat-foot, but on the other hand they exaggerate the severer forms, and the boots are entirely wanting in proportion. Zeising's law of proportion requires that the sole and the heel should have the relative length of three to two, like that of the normal foot.

In treating the deformities of the spine and legs incident to healthy girls, it is obvious that attention must be directed in the first instance to correcting the deformed knees and feet. The very first signs of the giving way of the arch of the foot, which is easily detected by examination, by growing pains, and especially a change of gait, should be met by the wearing of flat-soled, well-fitting boots, with indiarubber or felt pads inside to support the arch, and special exercises favorable to the development of the deep flexor muscles. At puberty, and for two or three years before, the growth is very vigorous, and in both stature and bulk girls shoot ahead of boys of the same age, the period of rapid growth of boys coming later. From ten to fourteen years the stature of girls increases at a uniform rate of two inches per year, except at thirteen, when it is two inches and a half, but the weight increases at a much greater rate. At ten years girls add 4 lb., at eleven 6 lb., at twelve 10 lb., at thirteen 12 lb., and at fourteen and fifteen 8 lb. to their weight, and this sudden addition to the weight tells rapidly on ankles, feet, and knees placed at a disadvantage by concurrent change in the position of the lower limbs by the evolution of the pelvis and the cramping of the muscles by tight boots. The arch of the foot often breaks down in the course of a few weeks, without warning or apparent cause, and in girls in perfect health, and especially those of an indolent habit. Fortunately the remedy is as easy and complete if applied promptly at the beginning and adhered to

persistently, as it is difficult and unsatisfactory if put off till the deformity is firmly established. Support to the arch of the foot prevents the formation of knock-knee and lateral curvature of the spine. When it fails to do so, the knock-knee can be corrected by the temporary application of long splints, especially in bed at nights; but no apparatus is necessary for the curvature of the spine in its earlier stages, as it will disappear on restoring the lateral balance of the body, and all treatment will be useless until this is done. Much walking or standing should be avoided, and short but vigorous gymnastic exercises substituted, and when possible the recumbent position assumed. Sitting on the ground or on a sofa in the cross-legged oriental position serves to expand the pelvis, evert the knees and invert the ankles, and counteract all the deformities; while sitting on chairs with the legs crossed one over the other directly favors them. It is probable that most children spend too much of their time on their feet, and that their powers of walking is very much overrated. Running is the natural gait of all young animals, and children always run if left to play by themselves. The dire effect of standing and walking in producing flat-foot in children is shown by the following statistics, taken from my paper on "Flat-foot" in the St. George's Hospital Reports (1872-4): Of 10,000 children between the ages of eight and thirteen years which were examined, about one-third were school children living in country towns and agricultural districts, another third were school children living in manufacturing towns, and the remainder were factory children. Among the first, 17.1 cases per 1000 of flat-foot occurred; among the second, 30.7 cases per 1000; and among the third—i.e., the factory children, who were employed five hours' daily standing, walking, and carrying weights—79 cases per 1000 of flat feet were found. Among the latter the deformity was found to increase rapidly with age—i.e., with the longer period of employment in factories. Thus:—

Of the age of 8 years, 15.1 per 1000 had flat-foot.

"	9	"	45.6	"	"
"	10	"	51.2	"	"
"	11	"	104.2	"	"
"	12	"	132.4	"	"

At the period when these observations were made (1873) children were allowed to commence work in factories at the age of eight years, instead of ten as now, and the low rate of 15.1 per 1000 represents the normal rate before the strain of labor has begun to tell on the children's feet.

There can be little doubt that children are made to stand and walk far too much both at home and at school. Standing at lessons, parade exercise, and much of the military drill in schools are injurious to both boys and girls, and especially to the latter. Instead of listless standing about, or taking long walks with adults, children should be permitted and encouraged to play lively games, which they will generally do even if left to themselves, to dance, and to perform short but spirited gymnastic exercises with apparatus. Exercises which develop the muscles of the feet and ankles, such as hopping and skipping, are especially necessary for girls; and still better than these are the admirable exercises preparatory to stage dancing taught at the National Training School for Dancing. These exercises are directed to the development of the muscles and the free action of the joints of the lower limbs, and are far preferable to the languid movements of ordinary dancing. For the development of the muscles of the trunk and arms the excellent system of gymnastics for girls recently established by a lady in various parts of London, with the approval, after careful and re-

peated inspection by myself, of Dr. Richardson, Mrs. Garret Anderson, and others, is all that can be desired. The Swedish and other exercises effected without apparatus are of little use, as idle and indolent girls who stand most in need of physical training easily comply with the form, but evade the spirit and hearty compliance which such systems demand. These systems lack motive to complete an exercise, while simple apparatus such as balls, dumb-bells, and bars compel it by keeping the end in view and giving an impetus to its performance. With half the care which mothers spend on dressing and decking-out their children, often in unsuitable clothing, they might, with a little help from their medical advisers, prevent most of the deformities which mar the physical beauty, comfort and health of their offspring; and no time seems more appropriate than the present for directing the attention of medical practitioners, and through them of parents, to the means of attaining these objects, as the short walking dresses worn by women and girls at the present time reveal to all of us to what a great, indeed unexpected, extent the ugly deformities of the feet and ankles to which I have referred exist, especially among the well-to-do and higher classes.

A SCHEME FOR THE MORE COMPREHENSIVE STUDY AND PREVENTION OF SO-CALLED ZYMOTIC DISEASES.

By THOMAS M. DOLAN, F.R.C.S. Edin.

PROVISIONAL OUTLINE.

THE theory of creative evolution has placed the study of the genesis of species on a scientific basis. The germ theory promises as much for medicine. A richer fruition will result if the germ theory be studied by the light of evolution. We have seen its application in the animal and vegetable world; it has been extended to the sociological aspects of life, etc. It may be applied with advantage to the study of disease. Disease is not an entity standing alone. It should always be considered in its relation to the cosmos. Buckle, in his "History of Civilization," vol. iii., p. 447, tells us that the great glory of Hunter as a pathologist was that he formed the grand conception of a universal pathology. Buckle says: "With him [Hunter] the science of pathology did not mean the laws of disease in man alone, or even in all animals, or even in the whole organic kingdom; but it meant the laws of disease and of malformation in the entire material world, organic and inorganic. His great object was to raise a science of the abnormal. He determined to contemplate nature as a vast and complicated whole, exhibiting indeed at different times different appearances, but preserving amidst every change a principle of uniform and uninterrupted order, admitting of no deviation, undergoing no disturbance, and presenting no real irregularity." In the views herein set forth there is then nothing new, except perhaps in the method in which they are set forth. It is one which has occurred to many minds. There is a tendency at the present time to consider disease in its relation to evolution. The papers by Dr. Airy, Dr. Roberts, Surgeon-General Gordon, and Mr. Millican indicate the direction in which this current is setting. The principle zymotic diseases are small-pox, scarlatina, measles, whooping-cough, diphtheria, cholera, and typhoid. We have evidence to support the view that these diseases are caused by micro-organisms. These diseases must be studied in the same way that the naturalist studies animals and plants. The naturalist, when

engaged in the study of the life-history of any individual animal or plant, looks in a broad-world point of view at his subject, and by the aid of evolution throws light on the genesis, distribution, development, transmutation, and varieties of each animal and plant. The scientific physician must approach the study of disease in the same way.

The following is an outline of what I believe should be done:—

1. *The Genesis of Contagium Vivum.*—Under this head will be included the life-history of each form, tracing it as far back as possible. Evolution does not tell us when each seed, as, for instance, that of the oak or ash, first appeared. We can only go as far back as the historical period extends; so we cannot expect to be able to reach the ultimate stage when each disease first appeared. Evolution fixes in what part of the globe each plant examined first appeared, as the scientist not only traces back to the earliest period its existence, but also, by the study of its habits, is able to determine the zone in which it could exist. As regards the genesis of each individual disease germ we must apply the general principles of evolution.

2. *Reproduction.*—Under this head will be considered the mode of reproduction, whether slow, or rapid, whether the seeds are derived from seed forms, or whether multiplication takes place by fission. Example: Drs. Dallinger and Drysdale's experiments on the life-history of some monads. These observations are models of what is wanted.

3. *Development, Maturity and Decay.*—Duration of life in each form of contagium. How long may it be preserved? Average period of existence in mature and embryonic form. Morphology and physiology.

4. *Laws Controlling Contagia, etc.*—Special seasons of activity; the influence of environment on each disease; sanitary conditions and relation to physical phenomena; influence of oxygen in the atmosphere; heredity, variations; crossing or transmutation; susceptibility; relation of the habitat; progressive development of types; application of analogy of laws regulating plant life.

5. *Distribution in its Geographical Relations.*—Influence of climate; atmospheric variations; warmth, moisture, winds, barometric, electric, thermic disturbance, etc. Secondary natural influences; currents; winds; animals, transport by. Effects of human interference. Example: Measles introduced into Fiji Islands. Migrations. Effects of cultivation by civilization. Effects of extinction of diseases by sanitation, similar to extinction of weeds in the plant world. Distribution of disease in zones. Relation of disease to flora and fauna. Natural selection for localities. Latitudes in which diseases are found. General method of diffusion.

6. *Geological Distribution.*—Nature of soil, sub-soil, alluvium, clay, etc.; rock. Mountain, valley, or plain; drainage; swamps; watershed; rivers; lakes.

GENERAL PREVENTIVE MEASURES.

These can only be secured by establishing, as it were, a sanitary cordon round the world, and by the combined investigation of disease by an international method—London, Paris, Berlin, Vienna, Brussels, etc., to be in communication, so that the heads of sanitary bureaus in each country may know the sanitary state of each country. This could be done by maps, charts, and records, to be framed and kept on a uniform plan. The incidence of disease in individuals and communities will be noted; sex, age, color, nationality will have their proper place assigned; sporadic, endemic, and epidemic states will be considered in relation to causation. Hygiene will thus be carried out in

a cosmic spirit; all those minor considerations as trades and professions will be examined in their relation to disease; whilst the value of food, pure air, water, etc., will be also appraised.

Vast statistics on almost every point connected with disease will by these means be secured, and conclusions drawn therefrom. Thus will be obtained the sum of the conditions of the causes and propagation of disease; thus will be found the varying effects of climate and other agencies; and, above all, we shall learn the value of preventive measures necessary for its eradication. We have not as yet in England arrived at an appreciation of some of the simplest elementary truths in reference to prevention; for instance, the notification of infectious diseases and hospital accommodation for them are two of the first essentials. They should be State regulations. Each town is now allowed local option as to what it shall do. It seems Quixotic to attempt a broader scheme in the face of the prevailing indifference or disregard for both these measures in England. Prevention and spread of disease are not only State questions, but they have a cosmopolitan interest. Now that communication between different countries is so rapid and so much facilitated by steam, the health of one country is of vital interest to all countries; causes operating in England may affect France and *vice versa*. For example, let us take the sanitary state of Hull. Hull is a seaport town. Let us look at the sanitary state of this town in the year 1881. In consequence of the prevalence of scarlatina the Local Government Board sent down Dr. Airy to inquire into the sanitary condition of the town. Dr. Airy held the inquiry on the 9th and 10th of March. The medical profession of the town submitted a memorial from which I extract a few items. The memorial sets forth that the outfalls of the sewers are blocked for sixteen hours out of the twenty-four, and that the ventilation of the sewers is most defective. The present mode of collection of night soil is very inefficient, being effected irregularly in open carts. Refuse is deposited in various parts of the town on unused plots of ground. The connection of houses with the main drainage is notoriously insufficient. New houses are not examined during the course of erection as to their drainage and other sanitary arrangements, and building sites are frequently formed by the filling up of disused brickponds with animal and vegetable refuse and street scrapings. The Artisans and Laborers' Dwellings Act and the Sale of Food and Drugs Act are not properly carried out, nor are the sections of the Public Health Act dealing with offensive trades and the smoke nuisance. A reservoir supplying water to the town is uncovered, though exposed to the foul emanations issuing from fish and bone manure works in close proximity. The hospital accommodation for cases of infectious disease occurring in the town is totally inadequate, especially in view of the special danger to Hull arising from its close and frequent communication with the Continent. Disinfection is not undertaken by the local authorities free of expense, and the charges which the Corporation make no doubt deter many people from having their disinfection properly done. There is no mortuary in the town, and the means adopted for the prevention of epidemics are generally inadequate. This is a sad picture in the nineteenth century. Hull in this insanitary condition is a danger to the world. She may distribute scarlatina by ships as well as wind and wave currents. At present health officers of different countries are ignorant of the general sanitary state of other countries. Under my system the state of Hull would be known. Perhaps a friendly communication might be made by some foreign State to the

Minister of Public Health in England to look after the sanitary state of Hull if this international system were at work.

My leading ideas are—1. That the sanitary authorities of each country should work on one uniform plan and under central direction. 2. That all sanitary authorities in every country should interchange maps, etc., and that the methods of recording disease should be the same. It is easy to draw up forms for international use. I have given one quotation from Buckle. I shall conclude with another, as an excuse for not tracing in detail the way in which diseases have originated or spread:—"To do this would require a learning and a reach of thought to which hardly any single man ought to pretend, since it is one thing to have a perception of a large and general truth, and it is another thing to follow out the truth in all its ramifications, and prove it by such evidence as will satisfy ordinary readers"—(vol. i., p. 131).

Halifax.

SOME OBSERVATIONS ON THE CONTAGIOUS DISEASES ACTS.

By RAWDON MACNAMARA, F.R.C.S.I.,

Senior Surgeon to the Westmoreland Lock (Government) Hospital, Dublin.

Of the many burning questions at present agitating our minds, perhaps there is none discussed with greater warmth than the propriety of retaining amongst our statutes the Acts of Parliament known by the name of the "Contagious Diseases Acts." Whether they should be abolished, retained, or even extended is discussed with an amount of energy approaching acrimony, calculated to excite surprise in the calm mind of a philosopher; and yet it strikes me that in all this controversy the question has been almost exclusively approached by those who would wish, not only their continuance, but their extension, from the man's side of the case, to a very great extent ignoring that of the woman; whilst the opponents of these measures seem to me to think that any beneficial results that may flow from such enactments are confined to the male sex—on their side also ignoring the woman in the discussion. Whilst at once avowing myself as an uncompromising opponent of the "billet de santé" system—an occupation in my opinion degrading to any respectable surgeon—still I should wish to point out, from the woman's standpoint of view, why it is that I should wish these Acts not only to be continued, but to be widely extended; and the facts which I shall submit in support of my views cannot be gainsaid—facts which, if called upon to do so, I can support by unquestionable documentary evidence. During the past five years our return of patients admitted into the Lock Hospital would show an average of 700 unfortunates annually admitted. Of these I am in a position to prove that 511 were reclaimed—something like one out of every seven saved from a life of sin!—225 sent to asylums, 88 reconciled and restored to their parents, 50 sent to the poor-houses, and 148 provided with respectable situations. All this good work due to the fact that their admission into the hospital brought them under the direct pious ministrations of our chaplains, the Rev. Dr. Gibson and the Very Rev. Canon Forde, whose exhortations, ably aided by our Matron, Mrs. Hogan, bore this good fruit. It would be but to abuse the patience of my readers were I to point out how inaccessible to such influences would have been these poor sinners were there no such hospital for their reception; and it is a matter for legitimate speculation how many

more might have been rescued were the Acts compulsory, thereby bringing a larger number under such influences.

So far I have been considering the subject from its moral aspect. I should desire now to say a few words upon the physical side of the case. How often have I wished when admitting these unfortunates into my hospital that some of the most earnest of the opponents of the Contagious Diseases Acts could be present to judge for themselves the amount of suffering they would inflict upon an erring sister by permitting her to ply her trade at a period when to do so must have been present torture and future misery. How often has the question been as it were wrenched from me, "My poor girl, why have you not applied ere this?" No one in general practice and unconnected with a Lock hospital can have any idea of the fearful condition in which from time to time patients are admitted into my hospital, which is situated in a city unfortunately not under the Contagious Diseases Acts. Were these Acts in force in Dublin, it would be simply impossible for such harrowing cases to present themselves. As it is, patients rarely present themselves in the earlier stages of their disease, when their treatment is manifestly more amenable. The effect of this on our general population, and more especially upon our garrison, it is unnecessary for me to point out.

Dublin.

ON A CASE OF PSORIASIS TREATED BY CHRYSOPHANIC ACID INTERNALLY.

By LEWIS W. MARSHALL, M.D.,

Surgeon to the Children's Hospital, Nottingham.

THE following case is of interest in connection with others published by Dr. Napier in *THE LANCET* a short time since, because, while I endeavored to act rigidly up to the rules laid down for the administration of chrysophanic acid internally by the author of the paper referred to, the result was not so favorable as could have been wished.

Sarah A. C—, aged thirteen years, was admitted to the Children's Hospital, Nottingham, on May 24th, 1882, having numbers of patches of psoriasis all over her trunk and upper and lower extremities, those on the legs being most numerous and the largest. They existed chiefly on the extensor surface of the arms and legs. She gave a history of having suffered from the rash for six months, when it appeared in small spots, gradually enlarging and becoming scaly. On the day of admission she was ordered the following diet and treatment:—One-third of a grain of chrysophanic acid, with a sufficient quantity of sugar of milk, three times a day, this powder to be used after a meal, and to be continued unless diarrhoea or vomiting ensued. Diet to consist of meat, and avoidance of farinaceous products.

May 25th: Vomited directly after powder last night (5 P.M.), when they were stopped, but resumed at 11 A.M. to-day.—26th: Vomited again last night; no pain or discomfort.—31st: Dose increased to half a grain three times daily; spots fading slightly.

June 5th: Dose increased to one grain.—19th: Vomited after the morning powder.—19th: Dose to be a grain and a quarter.—28th: Two-grain doses used; spots on hands less distinct; made outpatient, but to continue treatment.

July 1st: Spots improving, but not markedly so; has vomited twice since she left the hospital.—12th: States to-day that she vomits everything she eats, and the treatment was discontinued.—19th: An ointment of chrysophanic acid with vaseline

(twenty grains to the ounce) was used locally, after which rapid improvement was noticed.

Sept 8th: The patient was discharged well.—29th: To-day I have heard that the spots have not returned.

Nottingham.

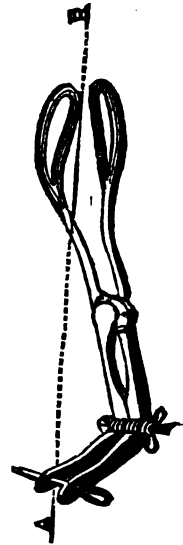

A NEW INDICATING AXIS-TRACTION FORCEPS.

By A. DRUMMOND MACDONALD, M.B., C.M. Edin.

THE leading points in the design of this instrument are—(1) axis-traction without the use of intra-vaginal rods; (2) indication of the grasp taken of the foetal head; (3) portability; and (4) minor deviations from the ordinary type of long forceps, partly suited to the three preceding points, partly by way of improvements. How this design is practically carried out is shown in the accompanying woodcut and following description.

Taking the parts *serialim*: (a) The blades are 6½ in. long, 2½ in. apart at the widest, and 1 in. apart at their extremities, which are not quite so broad as usual. When applied, and traction made, they will "give" half an inch, a point to be observed in all forceps, according to the temper of the steel, and having an important bearing on the question of grasp. The total breadth is 1½ in., the fenestrum being ½ in., leaving 7-16 in. steel, which ensures a good hold. The fenestrated portion has been made nearly straight, and the pelvic

curve lies in the lower portion of the blade and upper part of the shank, for the reason that when the blades are in apposition to the head, at or entering the pelvic brim, the natural curve of the genital canal lies below the head, consequently below the blades, and so corresponds to the curve above indicated. What we want is a pair of forceps acting as straight forceps, but without their perineal inconvenience, capable of being applied with facility, and at the same time adapted to the curve of the pelvic passages. (b) The shank measures 2½ in. (with the blade 9½ in.). This should prevent any locking in the vagina. (c) The lock is a kind of hybrid between the British and Continental locks, and allows of a scissors-action of the blades for the purpose of indication mentioned below. The lower blade has, and is easily recognized by, a hooked portion of the lock, on which the upper rounded and shielded segment is slipped in locking. (d) The handles have upper movable halves attached to the lower by a hinge joint which admits of their being folded down from right angles, so as to be easier of manipulation when required, and occupy smaller space when not in use. There are holes for a transverse traction bar through their ends, between which is a space for the middle finger to be passed through when grasping this bar. (e) The indicator is seen as a scale on the flat convex side of the binding-screw (c), passing through the centre of the hinge, and shows how far the extremities of the blades, when in position, are apart, within a range of one to three inches. This will indicate whether a sufficient grasp has been obtained to avoid risk of

slipping; and if the exact presentation and movement be taken into account, will give an idea of the measurement of the diameter of the head we are dealing with. For portability's sake the traction-bar may be screwed into the head of the binding screw. (f) Mode of application: The handle is not to be brought so far back towards the perineum as must be done with long forceps generally. Then having inserted the screw and read off its index number, raised the movable part of the handles, and placed in position the transverse bar, traction is to be commenced (assuming that the head is at the brim) with the bar opposite the tip of the coccyx, so that the line of traction (A B) shall pass through the axis of the brim. The hand is of course to be moved forwards as the head descends. The forceps are dark bronzed, to take away the formidable aspect that bright polished or plated instruments wear in the eyes of outsiders. Messrs. S. Maw, Son & Thompson have given me a ready assistance in carrying out my endeavor to produce an "instrument of precision."

Dingle-hill, Liverpool.

A WAISTCOAT-POCKET AURAL REFLECTOR AND SET OF SPECULA.

By E. CRESSWELL BABER, M.B. Lond.,

Surgeon to the Brighton and Sussex Throat and Ear Dispensary.

In comparison with some more favorably situated organs, such as the eye and the skin, the ear is placed at a disadvantage, inasmuch as it usually requires for the diagnosis even of its more common diseases the use of certain instruments. It is therefore of importance that these instruments should be made as simple and portable as possible. A great step in advance in this direction was undoubtedly made when von Tröltsch introduced into general use the aural speculum and concave reflector, by means of which an ear can be inspected either with daylight or artificial light. Under my direction Messrs. Millikin & Down, of St. Thomas's-street, Borough, have modified these so as to render them still more portable. The reflector (Fig. 1, reduced in size) con-

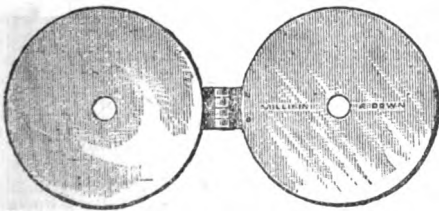

Fig. 1.

sists of two circular mirrors, each $2\frac{1}{2}$ inch (about 6½ centimetres) in diameter, and firmly jointed together at the edge, so that when folded their reflecting surfaces come into contact. One mirror is made of glass and is concave, having a focal length of $5\frac{1}{2}$ inches; the other is nickel-plated and plane. Both have a central circular aperture. With the concave mirror the ear may be examined either with ordinary daylight or with artificial light, whilst with the plane mirror sunlight may be reflected into the ear. The focal length of the concave mirror is purposely made rather long in order that it may also serve for an examination of the nasal cavities from the front, and for throwing light into the fauces in inspecting that region. With this reflector and a bent hairpin to draw out

the ala of the nose a very fair inspection of the nasal cavities can be made. The nest of specula (Fig. 2, natural size) consists of three, made of sil-

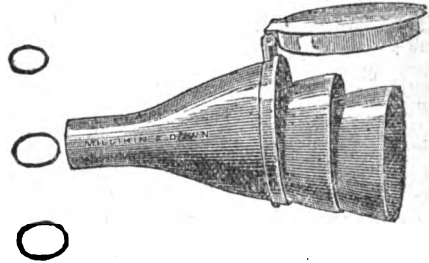

Fig. 2.

ver, fitting accurately one into the other. They are shorter than those in common use (measuring 3 centimetres—1½ in.—in length), and are made as light as possible. The smaller ends of the specula measure respectively about 6 by 7, 5 by 6, and 4 by 5 millimetres in diameter. The largest speculum, measuring at its broad end 17 by 18 millimetres in diameter, is fitted with a cap, which is preferably jointed on to the flatter side of the speculum, and not to the end of the oval, as shown in the figure. The shortness of the specula does not interfere, I have found, in any way with their practical utility, although, of course, they afford less leverage for moving them in the ear than the ordinary specula. With these two small instruments in his pocket, the practitioner can, at a moment's notice, inspect an auditory canal and gain important information as to the state of a patient's ear. Others, no doubt, like myself, have frequently been requested to look at So-and-so's ear, as he or she was suffering from earache or deafness. Instead of deferring one's examination to a future period, with these instruments at hand the auditory canal can be immediately examined, and the case prescribed for on rational principles. If, for instance, the meatus be occluded with cerumen, instillations of a solution of bicarbonate of soda can be ordered, which will facilitate its removal with the syringe at the next visit; if the meatus be filled with pus, directions can be given to syringe the ear with warm water; if the meatus be clear, and the membrane shows signs of acute inflammation, or of inflammation in the drum cavity, the immediate application of a leech in front of the tragus will probably be of great benefit, and any other instruments likely to be required, such as the Politzer bag or paracentesis needle, can be brought at a subsequent visit. Without multiplying instances, it is self-evident that, especially in acute cases, such as are met with in general practice, the earlier a case is examined the more successful and satisfactory the treatment is likely to be.

A CASE OF COLIC FROM UNUSUAL CAUSE.

By HERBERT FENTON, L.R.C.P., Etc.

On Saturday, Sept. 16th, I was called to see Mrs. H—, an Anglo-Indian lady whom I had attended in childbirth a month previously, and found her suffering from colicky pain of a particularly violent character, associated with distressing retching and vomiting.

The history the patient gave was that on the previous Thursday, whilst lifting a box, in weight about equal to a scuttle of coal, she felt a sudden sharp pain in the lower part of the stomach. No

notice was taken of this at the time, and the usual household occupations were continued until Saturday evening, though not without occasional twinges of pain. Physical examination showed the abdomen dull on percussion in the left iliac region, though there was no definite tumour on palpation. Elsewhere the abdomen was slightly tympanitic. Tenderness was complained of, and the pain was greatly increased by pressure. There were no signs of hernia. The pulse was 60; temperature normal. Tongue coated with a soft creamy but thick white fur, and the bowels had been opened once since the first feeling of pain on the Thursday. An ordinary effervescing mixture, with two drops of prussic acid (Sch.) in each dose, was prescribed, and turpentine stupes directed to be applied over the abdomen. No food, except a little milk, to be given. On Sunday morning the symptoms, with the exception of the vomiting, which was slightly relieved, were aggravated. An ounce of castor oil, with forty minims of laudanum, was then given, and the bowels were relieved about eight o'clock the same evening. One of the neighbors who was acting as nurse kindly washed and examined the motion, and found a splinter of wood two inches in length and about as broad as three matches. At the time of passing the motion most agonizing pain was experienced. After the passage of the wood the symptoms were all relieved, but what was described as a raw pain was still felt in the left iliac fossa. One grain of opium was then given every four hours, with a diet of milk and beef-tea. On the Monday there were signs of general peritonitis, which were speedily subdued by the free use of opium, and the patient then rapidly regained her usual health.

Remarks.—This case shows the necessity of carefully examining the motions in every case of intestinal obstruction, and also illustrates how the patient's own account may to a certain extent mislead; the pain experienced on lifting the box being perhaps a coincidence, perhaps due to some displacement of the previously innocuous piece of wood. The wood was probably swallowed with some French beans, which a boy who prepares them is accustomed to slice on the edge of the table, but at what time it was eaten is unknown.

Cumberland-street, S.W.

STONE IN THE BLADDER; RETENTION; SUPRA-PUBIC ASPIRATION; EXTRAVASATION; DEATH.

By O. A. INNES, M.D.,

Surgeon to Her Majesty's Prison, Hull.

W. L—, aged seventy-five years, came in as a prisoner on June 26th. He seemed a healthy, strong, well-nourished man, but stated that he had been troubled with gravel for the last ten years, and had to micturate every few minutes, night and day. Passed a No. 6 gum catheter, and found no stricture, but great enlargement of the prostate gland and irritability of the urethra. He applied every day at the surgery, and got a draught of solution of potash, hyoscyamus, and sweet spirits of nitre; which gave him considerable relief. About three ounces of slightly clouded urine were drawn off on July 8th, and tested with heat and nitric acid, but no albumen could be detected. On the 16th the symptoms were more urgent, and he was ordered in addition to the usual draught, a hot hip-bath. On the 17th he was reported as having had diarrhoea the whole night. I found him very prostrate, and complaining of great pain over the pubes, and of being able to pass his urine only by

drops. He had a hot bath and was at once admitted into the infirmary, and the following is the entry in the case-book.

July 17th: Attacked with diarrhoea during the night; urethra very irritable, and bleeds freely when an instrument is introduced; No. 6 silver catheter was passed with difficulty, but there was no urine in the bladder; complains of pain in the lower part of the abdomen when manipulated, especially over the left iliac fossa; his penis is very painful when touched. Prescribed an astringent mixture, one ounce, to be repeated every hour if necessary, with hot fomentations to the abdomen and the perineum. Ordered four ounces of brandy with low diet, and one pint of beef-tea.—18th: Very restless during the night; passes water very frequently, an ounce at a time; diarrhoea checked; to repeat fomentations, and have rice-water to drink, as he complains of thirst; tongue dry and furred.—19th: Slept better; bowels again troublesome during the night; he has less irritation of the bladder, but is feverish; his face is flushed, and he seems very restless and uneasy. Ordered astringent to be repeated, and poultices to be applied over the abdomen.—20th: Patient remains much the same; he passes his water by dribbles; he rests better at night, and his bowels are quiet; to continue treatment.—21st: Has passed no water since yesterday evening; on examination there was a large accumulation of urine in his bladder, extending as far as the umbilicus; attempted to pass a No. 6 silver catheter, but was stopped by prostate, which was found on examination to engage nearly the whole space of the outlet of the pelvis. 2 p.m.: Dr. Robertson kindly saw the case with me; after considerable difficulty we passed a prostatic catheter, but failed to draw off the urine; tried by injecting warm water to clear the catheter of clots, and also by fixing the nozzle of the aspirator to the catheter, but beyond the smell of decomposed urine nothing was sucked up; the catheter appeared as if wedged tightly in the bladder. 3.30 p.m.: All attempts to relieve the bladder per urethram having failed, we aspirated above the pubes, and only about one drachm of highly decomposed urine was drawn off.—22nd: Patient is in a very critical state; no urine has passed naturally for thirty-six hours, he has been partially delirious and very restless; towards morning his stomach became irritable; no change in the size of the abdominal tumour; has now got congestion of the base of both lungs. Dr. Robinson again saw the case with me.—23rd: The patient died at 5 p.m.

Mr. Henry Thompson, by order of the coroner, conducted the post-mortem examination, and has kindly placed his notes at my disposal.

Autopsy, twenty-three hours after death.—Body well nourished. Rigor mortis complete; blueness on depending portions. Head and chest not examined. Abdomen: One inch and a half above the pubes was noticed a punctured wound, the edges of which had made no attempts at union. Abdomen much enlarged, hypogastric and both inguinal regions appeared to be occupied by a doughy irregular mass, more prominent on the left than on the right side. Abdominal walls and omentum contained a considerable amount of fat. General peritonitis of intestines, especially on the left side, both gluing the intestines to each other and also to the bladder and pelvic walls. Liver natural. Kidneys large and pale, and studded with cysts. Between the bladder and the pelvis, behind the peritoneum, extending into the substance of the abdominal walls, and dipping down into the pelvis, was a mass of gangrenous cellular tissue infiltrated with urine, distended with gas, and containing some small calculi. On dissecting out the bladder a mass of calculi (105 in number,

and weighing 3 oz. 69 grains) was found sacculated in a distinct cavity to the left of the bladder, but communicating, through an opening large enough to admit two fingers, with the bladder itself. The summit of this sacculi had ulcerated or sloughed through, and the urine and some of the calculi had escaped out of it into the gangrenous mass previously described, and of which they were the cause. No calculi were found in the bladder itself. The walls of the bladder were hypertrophied, and the mucous membrane rugous, and in a sloughy state. The urethra was natural, but the prostate gland was much enlarged.

The case is interesting from the number of calculi sacculated and undetected, and from the puzzling and grave symptoms which developed themselves on the 21st July—viz., the suppression of urine, the size of the tumour simulating a distended bladder, and the unsuccessful attempts to evacuate the bladder. It is pretty clear that peritoneal inflammation had commenced on the 17th, probably occasioned or intensified by the diarrhoea which he had on the night of the 16th, and that perforation and extravasation took place on the night of the 20th. The tumour felt must have been the thickened wall of the bladder, with the inflamed visceral matters, and glued to it.

ON THE INTERNAL ADMINISTRATION OF CHRYSOPHANIC ACID IN PSORIASIS.

By H. E. CAUTY, M.R.C.S., etc.,

Senior Surgeon to St. George's Hospital for Skin Diseases, Liverpool.

SOME months since there appeared a rather long article in *THE LANCET*, in which the internal administration of chrysophanic acid in psoriasis was sufficiently favorably mentioned as probably to induce many gentlemen to give this medicine a trial. The list of remedies having any special cutaneous action is so limited, that any new one would, I think, be gladly welcomed by the profession generally, and it was the attributed possession of this specific power by the acid that merited attention in the paper above named, for it was stated that the idea of the internal use of chrysophanic acid was first suggested by observing that in a case where both legs were affected with psoriasis, both got equally well, though the acid as an ointment was only rubbed into one of them, the inference drawn being that the absorption of the acid and its subsequent constitutional action cured one leg as well as the other; the other deduction, that the acid had nothing to do with the disappearance of the disease, was not considered. There were a good many cases mentioned in *THE LANCET*, but on examination all were either fragmentary, incomplete, or unsatisfactory, but one, which was that of a boy seven years old, with psoriasis of two years' duration, who, after six weeks in hospital, was cured of the disease by gradually increasing doses of chrysophanic acid, taken not without sundry inconveniences, until at last two grains three times a day were supported. In this case, as in all the others, no mention is made of the state of the pulse, which in psoriasis is so important, for no case of this disease occurs in which the pulse is not either slower, smaller, or weaker than it ought to be, and any medicine which either ameliorates or cures this disease improves the pulse in either rapidity, volume, or strength. The favorable case was also young. In youth psoriasis is very common and comparatively less persistent than in after life, disappearing and returning eccentrically, from causes often slight and untraceable. However, it having been stated that chrysophanic acid had

some good qualities, it was tried in many cases, of which the three following are examples:—

CASE 1.—M. T—, aged seventeen, engaged in the boot trade. Tongue rather white and irritable, countenance flushed and thick; pulse 72; psoriasis guttata on arms, with some patches of twelve months' duration; very thin; regular.—July 19th: Half a grain of chrysophanic acid in sugar of milk three times a day after food.—23rd: Patches fainter; complexion clearer; tongue cleaner; was griped after taking the first powder.—20th: Took two powders; more griping and sickness four hours after the second powder. Bowels opened three times.—21st: Took two powders, was very sick, and had pyresis. Treatment changed to solution of bismuth, aloes as a purge, and then arsenic. This case was not encouraging, but as there were symptoms of irritable stomach at starting it might have been exceptional.

CASE 2.—E. B—, aged nineteen, machine worker, made her first appearance at the hospital on May 12th. This was a well-marked case of psoriasis nummularis; the tongue was rather white and bowels confined; conjunctivæ slightly yellow. She had in addition to the eruption four hard subcutaneous lumps in the calves of the legs, feeling like knotted veins, around which there had been some exudation, and which knots were extremely painful (thrombosis); pulse 72, weak. She was ordered potash and ammonia with podophyllin, which she took until June 2nd, when the swellings in the legs had nearly gone and the tongue was clean, the eyes being still somewhat tinged; bowels open.—June 2nd: On that date she began to take a quarter of a grain of chrysophanic acid three times a day.—5th: Conjunctivæ clearer.—9th: Dose increased to one-third of a grain.—11th: Scales falling off, swellings gone, tongue clean; pulse 84, full and soft; not at all the pulse of psoriasis. I now began to have hopes that there was some real benefit to be obtained from the acid, as there were no fresh spots, and the symptoms (though this stage has often been reached by many medicines) were generally better. The dose was increased to five-twelfths of a grain.—16th: These hopes were arrested, as though the bowels were open twice a day and the tongue clean, there were some fresh spots, slight papules, with some flatulence. Dose increased to half a grain.—19th: Dose three-quarters of a grain; tongue clean, bowels open, rash somewhat paler; pulse 84, weak; flatulent colic.—23rd: Dose one grain.—26th: No fresh spots, rash paler; hepatic pain under right shoulder.—30th: The legs have no more spots, but there is increased formation of scale; there are also fresh patches formed on the elbows, arms, and hands; pulse 72, fair; tongue clean; bowels open twice a day; these are now so sensitive that directly she takes her tea in the morning she has to hurry to relieve them. Notwithstanding that it appeared as if the chrysophanic acid had reached the utmost stage of toleration, I was desirous of seeing if a larger dose would have some effect on the eruption, and consequently having told her to discontinue the powders if the symptoms required it, the dose was increased to one grain and a half three times a day.—July 3rd: The powders excited great vomiting, and the scaly formation very much increased; pulse 72, full and soft; discontinued powders on July 1st. She was then ordered a carminative mixture, and afterwards arsenic, and is now nearly well. Notwithstanding that these cases showed no special cutaneous action of chrysophanic acid, yet thinking that there was some evidence of increased biliary secretion apart from simple purgative action on July 29th, I tried it in the next case.

CASE 3.—C. M—, a widow, aged fifty-seven, a large flabby fat woman with two large bright-red

patches of psoriasis, exfoliating large scales, covering one elbow and one knee, each patch being three inches square. Tongue foul and coated; pulse 72, weak; bowels confined. She began with half a grain doses of acid on July 28th, increased to three-quarters on July 31st.—August 1st: There is no improvement in either the rash or the tongue; the bowels are purged twice a day, and the powders have each time produced vomiting; the conjunctivæ are still mahogany color.

Observations.—The results obtained in these cases were not such as to encourage further trials, nor to confirm the supposition that there was any specific cutaneous action; on the contrary, it leads to the deduction that in the successful case published in *THE LANCET* the good result must have been due to continuous purging, and if this deduction is correct, then there are other medicines whose action is equally efficacious, and at the same time free from those irritating properties which characterize chrysophanic acid. In three other cases in which this was tried it acted so immediately as an emetic that it would be absurd to consider them in connection with a constitutional action. In the second case where the drug was tolerated better than in the others at the time when, if any, a specific benefit ought to have been manifested, the disease increased in virulence. It is possible that in future therapeutical works the acid will be quoted as a remedy for psoriasis, and in consequence it may be tried by many gentlemen whom the persistence of the disease has sorely puzzled; it is with a view of pointing out what results may possibly be expected that the foregoing cases have been recorded and sent for publication.

Note.—The name chrysophanic acid is retained in the above observations, but I am informed that the proper name is chrysarobin. This is the active principle or one of the active principles of rhubarb; and I notice in the *Pharmaceutical Journal* the active principle of senna, supposed to be cathartine, has been resolved into three substances, one of which is chrysarobin. The action of the so-called chrysophanic acid resembles very much that produced by senna and all its preparations on some individuals.

TREATMENT OF CHRONIC DYSENTERY BY LARGE INJECTIONS OF NITRATE OF SILVER SOLUTION.

By GEORGE E. POST, M.D.,

Professor of Surgery in the Syrian Protestant College; Surgeon to the Johanniter Hospital, Beyrout.

THE patient is a European lady who has lived for about eight years in Syria, aged about thirty years, of healthy constitution, the mother of three healthy children. Partly as the result of nervous prostration, and partly from lactation, she was attacked in the latter part of last autumn with pains in the back of the head and some confusion of the mental faculties. These symptoms, with persistent sleeplessness, continued until the beginning of the spring of the present year, when she was attacked with diarrhoea, which gradually assumed a dysenteric character. At the time when I first saw her, July 28th, her state was as follows:—Great general debility and nervous prostration, nausea, which was in part due to a mixture of catechu and other astringents which had been administered with a view of checking the diarrhoea; characteristic dysenteric evacuations, accompanied with severe colicky pains and abdominal rumbling and uneasiness. She was not at that time taking any precautions in diet, nor confining herself to bed.

There was no elevation of temperature, but the expression of countenance was haggard and worn. She was also much discouraged about her state, and harassed by sleeplessness, and in despair of recovery. The tongue was somewhat roughened by the astringents which she had taken.

I commenced the treatment by fifteen-drop doses of castor-oil, a strict milk diet, rest in bed, and ten-drop injections of laudanum in starch to quiet the tenesmus. This treatment was continued for forty-eight hours, with the effect of bringing away a few scybala, and relieving to a certain extent the tenesmus and nausea and slightly improving the character of the discharges. On the afternoon of August 1st an injection of three pints of water containing forty-five grains of nitrate of silver was prepared. The syringe was not, however, in good order, and not more than a pint entered the bowel. This was retained four or five minutes. It brought away with it mucus, greenish faecal matter, a few scybala, and a little blood. A good deal of pain followed, and lasted for about an hour before it quite passed away. Shortly after the first motion she had another free from scybala. An hour and a half later another more copious, with considerable pain; half an hour later a small one with little but mucus; a little later some bloody mucus. As pain continued a laudanum and starch injection was administered. Twenty minutes later she had a small brownish stool, with a little mucus. After this she slept for three-quarters of an hour, and awoke to have a small mucus passage, after which she vomited. An hour later a small motion. Still an hour later a brownish stool with some greenish admixture and little mucus. Five other motions occurred during the next seven hours, the last looking like ordinary liquid faeces. In the morning she was sick and vomited, but soon after, despite a few small motions, felt stronger. She took her milk and limewater better, and occasionally a teaspoonful of brandy. The headache had nearly passed away, and she slept fairly between the motions. No fever or quickening of the pulse. Abdominal pain much lessened. The history of the second day is briefly as follows:—Motions: 9 A.M.; 10, small but natural; 12.30 P.M., small but natural, with a little greenish slime; 1 to 3, four small motions, the last with specks of mucus; 3.30 to 6, two motions, the last small but natural; 7.30, small quantity of mucus. As there was some tenesmus without any passage an injection of starch and laudanum was administered, and half an hour later she fell asleep, and slept five hours, and awoke hungry. During the day the sickness of the stomach was much lessened, and she took and retained sufficient nourishment. In general she felt much better all through the day and night. During the remainder of the night of the second day she slept with little interruption. On the morning of the third day, at 6.30, she had a natural motion, but with it a little mucus and blood, and slight abdominal pain before passing. At 7 A.M. a copious natural motion; 1.45 P.M., small but natural, with a little mucus; 2.15 to 6, two motions like the former of this day; 6.15, a few scybala; 8.15, an injection of laudanum and starch (ten drops) was administered, after which she slept till 2 A.M., and again from 3 to 6 A.M., when she had a motion, not fluid and natural in color, with the addition of a small patch of bloody mucus. The fourth day, at 7.15 A.M., a small natural motion; 9, a little mucus; 3 P.M., a small natural motion, after which two pints of the above-mentioned solution of nitrate of silver were injected. She would not allow the whole three pints to be thrown in on account of the pain which they caused. The injection was retained less than a minute. It brought away with it less than the first, but some scybala, less than

before. She continued to have evacuations for three-quarters of an hour, the last being mucus without blood. The pain did not wholly cease for an hour and three-quarters, and then only after a laudanum injection. She continued weak and nauseated until 7 P.M., when she began to feel quite easy, and continued so until 9.15 P.M., when she fell asleep. After an hour of restless sleep she fell into a natural slumber, in which she continued uninterrupted until morning. No motions since 4.15 P.M. The fifth day was a good one. She was able to knit a good part of the day. She had one motion between noon and 1 P.M., with a little mucus, and another at 2 P.M. quite natural, semi-solid. She slept soundly during the night. She seemed to have caught a little cold towards morning, from insufficient covering, and complained of soreness in the bones, etc. It passed off, however, early in the morning of the sixth day. At 2 P.M. of the sixth day she had a small motion, quite solid. Began to long for food and experienced a hungry feeling, which the milk only took away for a short time. She took large quantities of the milk, but was not satisfied. She had neither pain nor ache, and the tongue was much cleaner. On the eighth day she began to take a little breast of chicken and soft-boiled eggs, and day by day her diet was improved. On the fifteenth day she had had no return of diarrhoea, had been up for three afternoons, walking a little about the room, and feeling stronger each day. Ten days having since elapsed without any further tidings, it may be inferred that she is now quite well.

As the treatment had to be conducted, after the first visit, by correspondence, at a distance of fifteen hours by messenger, some delay unavoidably occurred in advising the successive steps of the management of the case. Had the patient been within reach, I should have given the first injection a day sooner, and the second two days sooner. The return to a more nourishing diet might also have been slightly accelerated. On the whole, however, the case leaves little to regret, and nothing to desire. The very small quantity of laudanum required after the inauguration of the nitrate of silver treatment is most instructive. The easy and continuous sleep after such prolonged insomnia is also a feature worth noting. Any treatment which can cure so aggravated a form of dysentery as this one in so short a time, and with no drawback but the temporary pain of the injection, is an invaluable resource to the practitioner.

Beirut.

A VACCINATING INSTRUMENT.

By CHAS. EDWARDS, A.B., M.D., F.R.C.S.

THE instrument resembles a miniature subcutaneous syringe with needle, but differs altogether in application and partly in construction. It is supplied by Messrs. Weiss & Son, who have constructed it beautifully and most satisfactorily.

The following instructions must be understood and carefully attended to:—

1st. Prior to operating apply the stoma or apical aperture of the needle to the lymph well exuded from the vesicle of the vaccifer, then draw back a little the patent vulcanite piston. The instrument is thus charged somewhat beyond the basal aperture of the needle. The terms "basal" and "apical" I borrow from the extremities of the fang of the *neidr*. The instrument is now ready, by barely remoistening its point for as many instantaneous operations as are required.

2nd. How to operate: Do not gradually and

slowly introduce the needle-point, as with the lancet, but quickly and with the *neidr* stroke just beneath the cuticle. By this method you infallibly introduce the lymph, no blood, as from the lancet puncture possibly intermingling, and the small quantity of air between the basal aperture of the needle and the perfect piston when compressed by the "stroke," causing a reflex wave or rebound of the lymph into the puncture, thus sufficiently resembling, at least, in effect, the action of the anguine compressing muscles. A start of the patient, or any possible unsteadiness of the operator, is provided against by a beautiful little guard on the needle, by which too deep a stroke is rendered impossible. There is to be no injecting or even meddling with the piston during the operation, simply remoistening the needle-point.

The following are the advantages of this instrument: Rapidity, perfect introduction of the lymph, the absence of unsightly scars or scarifications so revolting to parents, however much they may be thought meritorious by others.

One word as to vaccination from arm to arm. If we must use the now conventional term ferment, and if the vaccine lymph be or contain this ferment, though it is not my wish to christen it or make a raid on the Greek prepositions to denote its successive results, still as all ferments act within a certain range of temperature there can be no temperature so sure for vaccine lymph as that secured by its coming from one living arm to another.

Cheltenham.

DISLOCATION OF THE UPPER AND LOWER ENDS OF THE LEFT HUMERUS BY THE SAME ACCIDENT.

By WILLIAM W. MOXHAY, M.R.C.S.,

Surgeon to the Royal Berks Hospital.

C. S., aged fifty-six, was admitted into the Royal Berkshire Hospital seven weeks previous to Sept. 4th, 1852, with a dislocation of the left elbow, the condyles of the humerus being thrown forwards over the radius and ulna. He had been struck at the back of the upper arm by the handle of a winch which was rapidly revolving. I was then house-surgeon to the hospital, but a medical friend acting for me reduced the dislocation, and all went on so well that the man was made an outpatient in a few days. On the above date he appeared and complained of some stiffness of the shoulder-joint on the same side; this, be it remembered, being seven weeks after the injury. I found the head of the humerus under the coracoid process, and I gave him one-grain and half-grain doses of tartarized antimony every ten minutes while extension of the limb was made downwards and upwards by means of pulleys. This went on for about half an hour, when he became deadly faint and could scarcely be kept in the chair. Extension was then suddenly left off and his elbow brought down over my knee as a fulcrum, when a sort of pop was heard and felt, and the bone returned to its natural position, only, however, to recede again to its acquired place. This was repeated once or twice on again replacing it, and at last we succeeded in fixing it in its proper position by a pad and bandages. He very slowly recovered, and on Sept. 25th was regaining some of the upward movements of the limb, and at his own request was discharged.

As far as my knowledge goes this is a unique case, and I think it may prove of interest, especially to some of the younger members of the

profession, who perhaps have never seen such use made of the powerful nauseant tartar emetic. Although it certainly enabled us to reduce a dislocation of the shoulder of seven weeks' standing, I would not now advise a return to such a barbarous practice, though it had the sanction then of the revered name of Sir Astley Cooper. With chloroform (at the time I have mentioned only just peeping out as a future friend in such cases), *nous avons changé tout cela*.

TONIC TREATMENT IN MITRAL DISEASE.

By J. BROWN, L.K.Q.C.P., L.R.C.S.I.,

Honorary Medical Officer to the Bolingbroke Pay Hospital.

THE following case is interesting as demonstrating the benefit derived from a tonic treatment in a case of dropsy, with regurgitant mitral disease, enormously enlarged liver, and albuminous urine.

Mrs. B—, aged forty-nine years, a widow, came first under my care as a private patient in August, 1881. She was then suffering from rheumatic arthritis and bronchitis. She had a distinct mitral murmur of old standing; her liver was very much enlarged, coming down half way to the umbilicus; there was no ascites, but considerable oedema of the ankles. She was a free liver, her usual stimulant being Irish whisky. She improved under treatment, which was continued for about three weeks. I did not see her again until she came under my care at Bolingbroke Pay Hospital on April 4th last. She then presented the following symptoms:—The valvular murmur was very distinct; she could not lie down on account of difficulty of breathing; her liver was very hard, and extended half way between the umbilicus and the pubis; there was considerable ascites, and her legs were oedematous to half way up the thighs; her urine was scanty and very albuminous; her skin was slightly jaundiced; temperature normal. All stimulants were stopped, and she was treated from April 5th to the 15th with a mixture containing digitalis, squills, carbonate of ammonia, and gentian; as the bowels were confined, compound jalap powder, forty grains, was given when required. No improvement being apparent, and as she seemed weaker, on the 15th a mixture of tincture of perchloride of iron and tincture of digitalis, of each ten minims, with glycerine, was given three times a day after meals, and was continued for nearly three months, most of which time she was kept in bed. In August all dropsical symptoms had disappeared; the liver was much reduced in size about two inches below the ribs, and no trace of albumen in the urine. All treatment was then stopped, but she remained in hospital until Oct. 8th. For the last six weeks she was able to walk several miles a day, which she had not been able to do for some years, and when she left the liver was still smaller, no trace of albumen, and she was gaining flesh, and slept well in natural position. I think this case bears out some of the ideas put forward by Dr. Leech in his introductory lecture to a discussion in Medicine at the last meeting of the British Medical Association.

New Wandsworth.

— Dr. A. J. Fuller, of Bath, U. S., reports a case of ascites which was tapped no less than forty-three times within a period of one year and three-quarters. The total quantity of fluid removed at the several operations was 1,420 pints. The patient, a married lady, aged sixty-five, died a fortnight after the last operation.

A Mirror OF HOSPITAL PRACTICE, BRITISH AND FOREIGN.

Nulla autem est alia pro certo noscendi via, nisi quamplurimas et morborum et dissectionum historias, tum aliorum tum proprias collectas habere, et inter se comparare.—MORGAGNI *De Sed. et Caus. Morb.*, lib. iv. Prooemium.

ST. THOMAS'S HOSPITAL.

MALIGNANT DISEASE OF THE PYLORUS; REMOVAL;
DEATH.

(Under the care of Dr. BRISTOWE and Mr. SYDNEY JONES.)

J. B—, aged fifty-seven, a stationer's assistant, was admitted into the hospital under the care of Dr. Bristowe on Sept. 22nd, 1882, with the following history:—He had always been healthy, never having had any serious illness, until the beginning of last May, when he complained of tightness over the upper part of the abdomen, with loss of appetite and inability to take fatty food without a feeling of nausea and regurgitation. From that time the feeling of tightness, with increasing soreness, of the region mentioned, had continued, and he had had occasional vomiting. He had also lost sixteen pounds in weight during the time. When admitted under Dr. Bristowe's care his condition was as follows:—Patient much emaciated, and complaining of pain in the abdomen on movement, followed by a feeling of sickness and of loss of appetite. On examination of the abdomen a hard, rounded, but somewhat irregular lump, from one and a half to two inches in diameter, is to be felt a little below the ribs on the right side, it is readily movable within narrow limits, and chiefly in the vertical direction; its centre is about an inch above and two inches to the right of the umbilicus. Its dullness is apparently continuous above with that of the liver, its lower edge extends from half an inch to an inch below the umbilicus. Its left border is about a finger's breadth, and its right border about four fingers' breadth, from the same part. It pulsates, but the pulsation is evidently communicated from the aorta. Liver dullness begins at the sixth rib, and is continuous with that of the growth; edge cannot be felt. Spleen normal. Tongue is a little coated. Appetite variable; no vomiting. Bowels open. Nothing abnormal in chest. Urine 1020; no albumen, lithates.—Sept. 6th: Was sick this morning for the first time since admission. Bowels regular. Sleeps fairly well at night.—27th: No further vomiting; felt a good deal of pain in the night, which he describes as a burning heat in the stomach.—29th: Patient feels easier this morning, has had no return of the sickness. Abdomen is not nearly so tender as it was.

Oct. 3rd.—Tongue coated, white, and dry; appetite good, bowels open. Complaints of shooting pains across the umbilical region, and distension after eating.—6th: The patient is expectorating a good deal, but there are no abnormal signs to be detected in the lungs. Resonance extends round the tumour, excepting perhaps for a short distance where it adjoins the liver. From this date until the 15th there was no marked change beyond the gradual emaciation of the patient and perhaps slight increase in size of tumour; he only vomited very occasionally, complaining chiefly of distension after food and slight pain in the tumour, which

was apparently lower down and more fixed, not moving with respiration. There had been no elevation of temperature whilst he was under observation.

The question as to the nature of the tumour was carefully considered and discussed from the time of the patient's admission up to the time of the operation. The possibility of its being an enlarged and diseased gall-bladder, a movable kidney, an aneurism, or a growth originating apart from the stomach in the peritoneum, had due weight given to it, and was fully argued out. The only one of the alternatives that seemed to deserve any serious consideration was that of its being a tumour originating in the great omentum or some other part of the peritoneum, and this would scarcely have deserved entertaining were it not for the fact that some of the most common and distinctive signs of pyloric disease were absent in this case. The patient while in the hospital enjoyed a fair appetite, he was very rarely sick, he never vomited blood, and the stomach was not greatly distended. Further, it was thought by some that the situation of the tumour was lower than could be well explained by its being a tumour of the pylorus. Dr. Bristowe, however, whilst admitting the possibility of its being a peritoneal growth, adhered to the opinion he had at first formed, that the case was one of carcinoma of the pylorus. The patient from the first expressed a strong wish to have the growth, whatever it was, removed. And considering that, notwithstanding his fair appetite, he was steadily growing weaker and thinner, at length it was determined to consult Mr. Sydney Jones with respect to the feasibility of an operation, and to put the matter plainly before the patient. The operation was not urged upon the patient, and the risk attending it was put before him clearly. He decided to have it performed. No doubt the patient would have lived some little time longer had his case been left to nature. But it was felt that any hope of benefit would be much greater now than if the operation were put off until the patient was sinking. In a former case, too, which had been under Dr. Bristowe's care, and the question of removal of diseased pylorus had been considered and determined upon, the patient only gave his consent when he was moribund, and too ill to have any operation performed.

Mr. Sydney Jones having agreed to operate, on the 15th of October the stomach was washed out with water, and from that date until the 17th he was only allowed skimmed milk, taking about two pints daily. The stomach was again washed out about an hour before the operation, which commenced at 2.15 p.m. of the 17th, and was carried out under the spray (1 of carbolic acid to 80 of warm water), and afterwards dressed with antiseptic precautions in the usual manner. Ether having been administered, Mr. Sydney Jones made an oblique incision extending from left to right, commencing an inch to the left of the middle line and four inches below the ensiform cartilage, four and a half inches in length, inclined downwards, carefully dividing the various layers until the peritoneum was reached, when, having arrested all hæmorrhage, the peritoneum was divided on a director to the extent of the previous incision. In the upper part of the wound, which gaped widely, the border of the liver was seen rising and falling under the costal arch with respiration, which was then jerky and irregular, whilst the growth was exposed about the centre of the wound. The gall-bladder was not seen. Slightly to the right of the middle line was a vertical band passing upwards to the liver and covered with a reflection of the peritoneum; this, which was the round ligament, was

divided between a pair of clamp forceps and both ends of a small vessel ligatured. Other peritoneal adhesions existed in this neighborhood. The tumour, which was larger than a duck's egg, was connected by numerous adhesions to the surrounding parts, and below it, close to the head of the pancreas, were a good many infiltrated glands about the size of small nuts. The great omentum was divided in pieces between double ligatures. The tumour being now more free, the stomach was lifted up towards its pyloric end, and flannels wrung out of warm water were placed under it to prevent bleeding into the peritoneal cavity. The lesser omentum connected with the pyloric end of the stomach was gradually cleared from the tumour by cutting between pairs of artery clamps and ligaturing both ends of the section. There was a good deal of hæmorrhage close by the head of the pancreas, for the most part venous. When the pyloric region was thus made more free, an opening was carefully made over the finger introduced from below in the lesser omentum to the left of the growth. The pyloric artery was then ligatured and divided. Then a Rydygier's clamp was put round the stomach by introducing one limb through the opening in the lesser omentum, and passing the other across the anterior surface; it was then closed, and the stomach divided to the right of it. The clamp was then removed, and hæmorrhage from the cut surface arrested; this was not considerable, only a few minute points requiring ligature; the stomach was found to be empty, and the mucous membrane appeared to be quite healthy. The cardiac end of the stomach was carefully sponged out. A little brownish fluid was seen at the pyloric orifice; a small sponge was placed in each orifice. The clamp was next placed on the duodenum just beyond the tumour, and the growth with some infiltrated and adherent glands removed. The duodenum was firmly held up when divided to prevent retraction. The growth was seen to extend a little further down the duodenum on its posterior border, so a small piece, including this, was removed by scissors. There was very little hæmorrhage on removal of the clamp, and a few fine ligatures proved sufficient. The upper part of the duodenum was mopped out, and a clean piece of sponge introduced. As the section of the stomach was larger than that of the duodenum, the upper part of the former was stitched together, for about two inches, by means of nine sutures of fine carbolized silk, through its mucous membrane, and a corresponding number of the same material, including muscular and peritoneal coats. The cut ends of the stomach and duodenum were now brought into apposition, and corresponded well in size. The posterior part of each was then sewn together with fine carbolized silk, the mucous membrane being carefully adjusted last, the first sutures applied being passed between the mucous and muscular coats, perforating the latter and the peritoneum, and then passing through the peritoneal and muscular coats of the apposed edge; as the opening became smaller it was not found possible to pursue the same plan towards the front, and here Lambert's stitches only were used. There were about fifty-two silk sutures put into the stomach and duodenum. The parts around were carefully cleansed, the flannels having been removed, and the stomach placed in position again. The external wound was closed by means of seven or eight deep silk, and four superficial catgut, sutures. During the course of the operation, which lasted almost three hours and a half, the patient became much collapsed, and it was found necessary to bandage his limbs and administer a brandy enema. After he was put to bed, in addition to the above

means, hot blankets and hot-water bottles were applied, and another brandy enema given. He became conscious about 8.30 p.m., complained of pain and asked for morphia, but gradually sank, dying at 11.15 p.m.

A post-mortem examination was made on the following day by Dr. Sharkey. The body was much emaciated. Rigor mortis well marked in both extremities. Pleurae adherent by old adhesions, at left apex and right base. Lungs a little collapsed, otherwise normal. Pericardium and heart natural. Liver small and pale, at the upper border of its right lobe was a nodule of new growth about as large as a walnut. Kidneys normal. On opening the abdominal cavity, by enlarging the incision of operation, the peritoneum looked almost normal. All that was remarkable was some dotted hemorrhages about the pyloric end of the stomach, and an exceedingly small quantity of red fluid on the surface of the coils in the neighborhood. One could scarcely see without close examination that any operation had been done, as the stomach, colon, etc., occupied their normal positions, and the stomach had its normal shape.

The carcinomatous growth removed measured one inch and a quarter along its upper border, and three inches and a half along the lower, its base was of a firm fibrous character, completely surrounding the pylorus and adjacent portions of the stomach and duodenum, and the inner aspect presented a fungating ulcerative surface, the lumen of digestive tract at this point only just permitting the passage of a small finger.

POPLITEAL ANEURISM CURED BY THE USE OF ESMARCH'S BANDAGE, FOLLOWED BY DIGITAL PRESSURE.

(Under the care of Mr. SYDNEY JONES.)

W. H. E—, aged thirty, a clerk (formerly a farmer), was admitted under the care of Mr. Sydney Jones on June 19th and discharged cured on July 19th, 1882. Three years ago he was under Mr. Sydney Jones' care for disease of the right elbow joint which was excised. Ten weeks before admission, after straining himself whilst running, he noticed stiffness in the left leg, increased by walking. Two or three weeks later he began to notice considerable throbbing pain behind the left knee, shooting down into the calf of the leg; this was very violent at times. About a week later he noticed a throbbing swelling behind the same knee. He went to a medical man and was treated for a fortnight by flexion of the knee joint and rest in bed, but for the last fortnight has only been resting without special treatment; there has been no improvement in the swelling. The patient, a tall, strong man, with reddish hair and beard, complained only of the swelling behind his left knee and the pain caused by it. On examination this swelling presented the characteristics of aneurism of the popliteal artery, and was about the size of a large hen's egg, and similar in shape. There was marked expansile pulsation, arrested by pressure on the artery, above, and a loud bruit. Its long axis corresponded with that of the artery, and it occupied chiefly the lower part of the space. The circulation was irritable, the pulse being full, quick, and rather hard. No evidence of arterial degeneration in other parts of the body. Examination of urine showed absence of albumen. The right elbow was ankylosed, but in a good position, and patient was able to feed himself comfortably, easily reaching his mouth with the hand. The morning after admission he was given three minims of tincture of aconite in an ounce of water, and this was repeated three times daily until the 23rd, when his pulse was quieter and more compressible. At a quarter before 3 p.m. on the

24th Esmarch's elastic bandage was applied, the patient standing up to allow the sac to fill. The bandage was applied gradually from the toes upwards; the aneurism, however, not being included. The bandage was fastened round the upper part of the thigh. The elastic ligature was not used. This was kept on for one hour and a quarter, and during the last half of the time it was necessary to keep patient partially under chloroform. When the bandage was removed pulsation recommenced, so digital pressure was at once started, and kept up for eleven hours, when all pulsation had ceased; at the end of nine hours the pulsation had much diminished, but did not stop until two hours later. During the last three hours patient vomited considerably.

June 27th: No return of pulsation. The aneurism much smaller. Several branches of collateral circulation detected. The general condition of patient good.

July 4th: Left foot still a little colder than the right. Pulsation of the posterior tibial artery indistinct. Is still kept in bed with his left leg semi-flexed and placed on its outer side. An elastic stocking was ordered, reaching from the toe to above the middle of the thigh. A few days later the patient was allowed to get up, and left with the aneurism cured on July 19th. As regards internal treatment, tincture of aconite, given on the 19th, was stopped on the 23rd, and from that date until July 1st he took ten grains of iodide of potassium three times a day. On July 1st the aconite was repeated, and the patient took a similar dose for a few days.

INJURY TO THE HEAD, IN WHICH RECOVERY OF CONSCIOUSNESS WAS FOLLOWED BY RELAPSE AND DEATH TWELVE DAYS LATER, AND IN WHICH NO CEREBRAL LESION COULD BE FOUND POST MORTEM.

F. S—, aged seven, was admitted, under the care of Mr. Sydney Jones, on Jan. 6th, 1882, with the following history:—At 4.30 p.m., on the 5th he fell over the balustrade at home, striking the nape of his neck on the stair. Before the fall he had been in his usual health. Immediately afterwards he lost consciousness, and remained unconscious for about three hours. He is then stated to have recovered, and recognized his parents. He complained of pain at the back of his head, and vomited two or three times. Later in the evening he again became unconscious, and was stated to have had fits, which continued at intervals during the night. During these attacks he struggled violently, screamed out, and ground his teeth; he also vomited frequently.

When brought to the hospital next morning he was in one of these attacks, and was restrained with difficulty, screaming out loudly and grinding his teeth. There was a slight bruise at the back of the neck, and on pressing over or near this the convulsive movements were set up. There was no sign of fracture of the skull. The pupils were very large, equal, not acting to light, but varying in size at times. Temperature 101°.

Jan. 7th: During the night he had occasionally tossed himself about in bed, and screamed out. He had only taken a few teaspoonfuls of milk and a purge. In the morning he was still unconscious, with a dry tongue and mouth. He was rather irritable, lying on his side, with his limbs flexed, and resisting any attempt to examine him. Pulse 100, weak. The temperature, which last night was 100°, was now 101.6°.—8th: The patient still lies in an unconscious condition, making only slight movements occasionally, and these principally on the left side. The left hand appeared the colder, but when tested by the surface thermometer showed

little difference: right, 97° 6'; left, 97° 4'. His breath was foul. There were sordes on the teeth. The pulse was 108, almost imperceptible, and intermittent: temperature of body 102° 8'.—10th: He slept quietly during a good part of the night, and in the afternoon showed some signs of returning consciousness, making an attempt to put out his tongue when told to do so. He slept a good deal during the day, but was very restless, tossing about from side to side when awake; the mouth was cleaner, he drank milk in fair quantities, but his pulse was extremely feeble and his hands cold: the temperature, morning and evening, was 97° 8'. 11th: No further improvement. He had taken beef-tea, jelly, milk, and a little brandy. In the afternoon the pulse was 148, almost imperceptible, and he was very restless, whilst the pupils were still equal, and there was no evidence of optic neuritis. Later in the day he became more restless and violent, throwing himself about, and knocking his head against the head of the bed; morning temperature 97°. Two nutrient enemata were given.—12th: Passed a fairly quiet night, and this morning appeared to recognize his parents, but did not speak. Morning temperature, 96° 8'; evening, 96° 8'.—13th: Appeared to understand, and protruded tongue when told to do so. Morning temperature, 97° 2'; evening, 98° 4'. Took more fluid nourishment and a little custard pudding. A blister was applied to the nape of the neck; and dressed with mercurial ointment.—14th: Temperature still subnormal.—15th, 11 p.m.: Extremities cold. Pulse running, at times almost imperceptible. The respiration, which had been slow and sighing, was then rapid and difficult. Had taken food well. Morning temperature, 97° 2'; evening, 98° 4'. During the 17th he appeared somewhat better and more conscious, taking a fair amount of food. About 12 o'clock at night he became worse, and his extremities very cold. A nutrient enema which was given was not retained, but he took some brandy, milk, and egg by the mouth; after this there was an action of the bowels, but no general improvement; and he died quietly at 4.45 a.m. on the 18th.

The post-mortem examination did not throw any light upon the case. The brain appeared in every respect natural, excepting that the organ contained rather more blood than usual, the puncta vasculosa being well marked. No hæmorrhage; no meningitis; no tubercle; no sign of softening. Skull and vertebrae without sign of injury; and cervical portion of cord apparently healthy. In the anterior border of left lung there were a few patches of broncho-pneumonia; lungs and internal organs otherwise normal. It is regretted that no microscopic examination was made of the nerve structures.

MIDDLESBY HOSPITAL.

SPONTANEOUS RUPTURE OF HEART; SURVIVAL FOR FORTY HOURS; AUTOPSY; REMARKS.

(Under the care of Dr. S. COUPLAND.)

For the following notes we are indebted to Mr. Alan E. Tate, resident physician's assistant.

W. T—, a gilder, aged sixty-five, was admitted into the hospital, Oct. 13th, 1882, with the following history. He had that morning gone to his work apparently in his usual health. About 11 a.m., while he was walking along the street, a heavy lamp fell close to and almost upon him. Though he was not struck he was startled very much. Three-quarters of an hour later, and after he had walked fully a mile further, he was seized with "a sudden pain all over the chest," and im-

mediately after fell down in a fainting fit. He was found in this condition by a policeman, who at once took him to the hospital.

On admission into the Founder ward, at noon, he presented all the symptoms of the most extreme collapse. The whole body was cold and bathed in a profuse cold sweat. There was extreme pallor of face and lips; the radial pulse was only just perceptible, and the heart-sounds were quite inaudible. No increase in the cardiac dulness could be detected, but both lungs were evidently emphysematous. His mind was quite clear, as he answered questions readily, and gave a coherent statement of the morning's events. There was no paralysis. Within the next half hour he vomited several times, and there was constant tenesmus; once his bowels were opened well.

The patient was seen soon after admission by Dr. Coupland, and some internal hæmorrhage seemed probable. Cardiac rupture was surmised, though in the absence of any positive proof, such as an increase in cardiac dulness, and looking to his desperate state, a stimulant treatment seemed the only course indicated. A mustard poultice was accordingly applied to the præcordia, hot bottles were put to the feet, two ounces of warm brandy-and-water were at once administered, and the following mixture was ordered to be taken every hour: Spirits of ether and aromatic spirits of ammonia, of each half a drachm, and one drachm of syrup of tolu in water. Half an ounce of brandy was also given every three hours. Under this treatment the patient slowly, but steadily, rallied. At 5 p.m. the pulse was distinctly perceptible at wrist, and the heart-sounds were faintly heard at apex, free from bruit; surface of body comparatively warm. Temperature 96° 6'; pulse 76; respiration 25. About this time he complained of pain in the right ankle, and a fracture of the lower third of the fibula was detected and at once set. The fracture was believed to have occurred in the syncopal attack. At 11 p.m. the same night the pulse was full and strong, 96; heart sounds moderately loud; lips and face a fair color; body and extremities warm. The stimulants were diminished in quantity and frequency, but still continued.

The next morning (Oct. 14th) the following note was made:—"Temperature 98° 6'; pulse 84. Slept at intervals during the night; has completely rallied from collapse. Skin warm; pulse of good volume and steady, but hard; heart sounds fairly well pronounced. There is some bulging of the left front of the chest in the præcordial region." Strict rest and stimulant treatment were continued, and all went well till 6 a.m. the following morning (15th), when, after a good night's rest, the patient became suddenly collapsed and died.

At the autopsy, which was made by Dr. Fowler, the following conditions were found: The cartilages of the third, fourth, and fifth ribs on the left side were prominent and arched. Those on the right side were flattened. All were calcified. On opening the pericardium about one ounce and a half of fluid blood escaped, and the heart was seen to be invested with blackish-red blood-clot, having a smooth outer surface. The clot was not adherent to the parietal pericardium. This clot was separable into two distinct layers, the outer of a rather paler tint and firmer. Each layer was removed separately, and found to weigh about seven ounces, some soft black clot at the back of the sac being weighed with the inner and probably most recently extravasated portion. The anterior surface of the heart showed a considerable excess of sub-pericardial fat. On turning the heart over, a rent half an inch long was seen in the posterior wall of the left ventricle, two inches and three-quarters

above the apex and one inch to the right of the posterior coronary artery, having an oblique direction. A probe passed through the rent emerged into the left ventricle, just behind the apex of the posterior papillary muscle. The posterior coronary artery could be felt as a rigid cord, and the pericardium having been dissected off, it was seen to be extremely atheromatous and calcified. A branch of the vessel (not found) had apparently ruptured, as there was some blood extravasated beneath the pericardium and deeper in the fat and muscular tissue around the vessel for a distance of three and a half inches. The anterior coronary artery was also atheromatous. The right cavities contained some post-mortem clots, and the left ventricle also contained a small post-mortem clot. The mitral and tricuspid valves were somewhat thickened and fibrous; the aortic were atheromatous. All were probably competent. The muscular tissue of the heart was soft, brown, and greasy; that of the right ventricle encroached upon by the subpericardial fat. The aorta was atheromatous. Both lungs were emphysematous, and very oedematous.

Remarks by Dr. COUPLAND.—Perhaps the fullest information concerning Rupture of the Heart in literature is that given by Dr. Quain in his Lumleian lectures (*THE LANCET*, 1872,) where he states that in 77 out of 100 cases there was fatty degeneration of the heart wall, and that 63 of the patients were above sixty years of age. He also points out what all writers, from Morgagni downwards, have noticed, that the exciting cause of the rupture is some sudden mental excitement or physical effort. In each of these particulars the case above recorded conforms to the general rule, but it may be added that until the day of the attack (which was distinctly referable to a violent mental shock) he had suffered no symptoms pointing to the existence of cardiac disease. Yet the coronary arteries were advanced in calcareous degeneration and there was considerable adiposity of the heart wall as well as true fatty degeneration. The case also resembles the majority in the lesion being in the left ventricle, but it is somewhat exceptional in the position of the rent, which in most cases has been found in the anterior wall, either in the region of the apex or close to the septum. In this case the rupture, which formed an oblique slit, occurred in the posterior wall at some distance from the septum, and about midway between the apex and base. This localization of the lesion was, no doubt, determined by the disease of the coronary artery and its branches impairing the nutrition of that part of the wall. The case is further of interest in the prolongation of life after the occurrence of rupture. According to Dr. Quain, "in 71 out of 100 cases.... death was sudden, occurring within one or two minutes. One patient, however, lived eight days, 1 six days, 1 three days, 5 lived over forty-eight hours, 3 lived under twenty-four hours, and 19 under twelve hours." In the present case, so complete was the rally under stimulant treatment that the idea of cardiac rupture, at first entertained, was thought to be beyond the mark, and that the case was, after all, one of temporary cardiac inhibition, from the influence of mental agitation. The sudden death, forty hours later, proved the correctness of the original surmise; whilst the discovery at the post-mortem examination of two distinctly separable layers of clot around the heart demonstrated the fact, that the rent had been temporarily closed after the first occurrence of hemorrhage. A very important question is here raised; admitting the impossibility of recovery after cardiac rupture, would life have been more prolonged had sedative treatment (as insisted on by writers on the subject) been pursued? This may well be doubted, for although,

on *a priori* grounds, it may seem wrong to stimulate to further action the heart so injured, it may equally well be contended that the ventricular contractions would aid in the temporary closure of the rent; whilst on the other hand continuance of the hemorrhage might be favored by measures tending to prolong the state of diastolic relaxation. In following the indications for prompt stimulation, as the only measure likely to rescue the patient from imminent death, this line of treatment was deliberately adopted in face of the possibility of such a lesion as actually existed. Had stimulants been withheld the man must have died in the first seizure, and in such a case a respite of a few hours may often be of great moment. The inference is that in similar cases—where diagnosis may be even more certain—the natural indication to administer stimulants may not be so harmful as is generally assumed.

RADCLIFFE INFIRMARY, OXFORD.

CASE OF UNUNITED FRACTURE OF THE HUMERUS IN AN OLD MAN SUCCESSFULLY TREATED BY RESECTING THE ENDS OF THE BONES AND FASTENING THEM TOGETHER WITH A PROBE.

(Under the care of Mr. HORATIO P. SYMONDS.)

WILLIAM S—, aged sixty-one, admitted on July 5th, 1882, with an ununited fracture of the left humerus. On March 15th he had been run over by a cart, the wheel of which, passing over his arm caused a simple fracture of the humerus. It was at once put up by a surgeon in the country with a rectangular and slide splints, and left without being touched for seven weeks. At the end of this time no union having taken place, the splints were readjusted at intervals till his admission.

When admitted there was an oblique fracture about the middle of the shaft of the humerus below the insertion of the deltoid. The fragments were perfectly movable, no callus having been thrown out. The man was in feeble health, appearing prematurely old. The circulation in the extremities was very weak, the hands being always cold and blue. There was no marked rigidity of the arteries, and the urine was free from albumen. The arm was fixed in a plaster-of-Paris apparatus for six weeks. When this was removed the condition was precisely the same as before. The patient complained greatly of the discomfort of the arm, and was willing even to have it removed. Under these circumstances, and notwithstanding the debilitated condition of the patient's health, it was thought advisable to try some operative procedure.

On Aug. 22nd, the following operation was done, with all antiseptic precautions. An incision three inches long was made on the outer side of the arm over the seat of the injury. The ends of the bones were cleared from the surrounding tissues and made to project through the wound. The periosteum was stripped from the ends for about an inch. A small slice of bone was then sawn obliquely off the ends of each, and a hole was drilled through from one to the other. Through this hole a silver-plated steel probe was passed (acting like a hare lip pin), and the ends being drawn together, was fixed by a stout silver wire twisted round the probe in figures of 8. The ends of the wires and the probe were left projecting from one end of the wound, the edges of which were closed by a few silk sutures, and dressed in the usual way. The arm was then fixed by a leather splint, having a steel bar from the elbow to the shoulder

in the outer side and an angular splint on the inner side.

The patient went on very well, the temperature only once, four days after the operation, rising above 100°. The arm was dressed at first on alternate days, afterwards at longer intervals. The antiseptics were left off on Sept. 20th and on Oct. 14th (two months after the operation) the probe was withdrawn without difficulty. It was found that considerable, though not perfect, union had taken place. On admission the arm was quite useless. Now he was able to raise it to a level with the shoulder; he is quite free from pain and has improved in his general health. A small fragment of necrosed bone came away with the probe.

LIVERPOOL ROYAL INFIRMARY:

TWO CASES WHERE BOTH BREASTS WERE REMOVED FOR CARCINOMA; REMARKS.

(Under the care of Mr. REGINALD HARRISON.)

CASE 1.—Mrs. McC—, aged fifty-one, was admitted on Oct. 27th, 1881, with the following history:—About twelve months previously patient noticed a slight hardness in the left breast, which was followed in six weeks by retraction of the nipple. Shortly afterwards a similar hardness commenced in the right breast. The patient was a healthy looking woman, married, with one child. In each breast there was a well-marked scirrhus carcinoma, with retraction of the nipples, but no extension into the axilla. On Nov. 2nd Mr. Harrison removed the right breast, and on Dec. 7th, when the patient had completely recovered from the first operation, the second breast was removed. On Jan. 5th, 1882, she was able to leave the infirmary, the wounds having completely healed. In the October following the patient reported herself as being quite well, and without any sign of a return of the disease.

CASE 2.—Mrs. R—, aged fifty-two, was admitted in November, 1881, suffering from a scirrhus carcinoma of the right breast with retraction of the nipple. The hardness had been noticed for eight months previously. She had a very healthy appearance. There were no enlarged axillary glands. On the 25th the breast was removed, and in nine weeks the patient was able to leave the infirmary. She seemed very intolerant to the carbolic applications. In June, 1882, she noticed some hardness in the other breast, but nothing was done, as she thought it was inflammatory and would disappear. In September she returned to the infirmary, when the left breast was found extensively infiltrated with cancer. The axilla was free. On September 13th, 1882, the breast was removed by Mr. Harrison. She made a good recovery, and was able to leave the infirmary on October 27th.

Mr. Harrison remarked that these were the only two instances in his practice where he had removed both breasts for scirrhus. In both cases the patients presented a singularly healthy and robust appearance, in fact, to look at them before making an examination of the breasts he should have selected them as typical examples of what healthy-looking middle-aged women should be. Still, there could be no doubt, either on clinical or histological grounds, that they were seriously infected with cancer. So far as the operations were concerned, no patients could have done better. Antiseptics were employed, and no untoward symptoms were met with. The second patient on each occasion showed an intolerance to carbolic acid, which rendered its abandonment necessary before repair had sufficiently advanced; still, she made an ex-

cellent recovery. Cases of this kind were interesting, not only as illustrating what operative surgery is capable of doing in the case of rapidly growing tumours, but as bearing upon the whole subject of infection by malignant growths.

PUBLIC HOSPITAL AND DISPENSARY, SHEFFIELD.

SEVERE WOUND OF THE ANKLE JOINT; RECOVERY WITH MOVABLE JOINT.

(Under the care of Dr. KEELING.)

For the following notes we are indebted to Mr. G. F. Gubbin, house-surgeon:—

W. H—, a boy, eight years of age, was admitted on Aug. 8th, 1882, with an extensive wound of his left ankle-joint posteriorly, caused by the cutting portion of a mowing machine. On examination it was found that the wound extended across the back of the joint, from below the internal to the external malleolus, the lower portion of which was separated from the rest of the bone and broken into fragments; the tendo Achillis was completely divided, as well as the peroneus longus and peroneus brevis muscles on the outer side. The joint was laid open and the cartilaginous surfaces of the bones entering into its formation exposed; some of the cartilage had been chipped off. There had not been much bleeding. Under the carbolic spray the wound was freed from fragments of bone and cartilage, and carefully cleaned; the two ends of the tendo Achillis were brought into as close apposition as possible, and fixed with carbolized catgut sutures. The wound was then sewn up with silver wire and catgut sutures, and enveloped in the ordinary antiseptic gauze dressing, the limb laid on its outer surface, and the ankle-joint fixed in the extended position. The wound was dressed twice during the first eight days, afterwards once a week until Aug. 30th (or twenty-two days after the receipt of the injury), when it was found to be quite healed. The boy was kept in bed and passive movement practiced.

On Sept. 11th he was able to flex and extend the joint freely, and to invert the foot, but the power of eversion was rather weak; he was not able to bear much weight on the limb. He was now allowed to get up. The boy continued to improve, and on September 20th it was noted that he could get about with ease, although not able to bear the whole weight of his body upon the injured limb. When he was lying on the bed it was found that he could move the wounded joint just as freely as the sound one.

Medical Societies.

PATHOLOGICAL SOCIETY OF LONDON.

Congenital Malformation of Heart.—*Paraplegia.*—*Disseminated Sarcoma.*—*Xanthoma Tuberosum.*—*Pigmentation of Uterus.*—*Empyema from Foreign Body.*—*Malformation of a Lamb.*

THE ordinary meeting of this Society was held on Nov. 7th, Dr. S. Wilks, in the chair. The report of the committee appointed at the last meeting to examine Dr. Norman Moore's specimen of deformity of the heart was read to the Society. The specimens shown by Dr. Kesteven and Dr. Hadden were referred to the Morbid Growths Committee. Dr. Malcolm Morris read a very complete account of a remarkable case of skin disease, his

designation of which—*xanthoma tuberosum*—was not accepted by the other dermatologists present, who, however, did not suggest any other name for it. The case was referred to the committee which last year reported upon *xanthelasma*.

Dr. Pye-Smith read the report of the committee appointed to examine Dr. Norman Moore's specimen of narrowing of the left ventricle below the aortic valves. The committee could not decide whether it was congenital or acquired, but were of opinion that the fibrous ring was of later date than the formation of the aortic opening and septum ventriculorum, and of earlier origin than the aortic aneurism, and therefore they referred it to the later period of intra-uterine life.

Dr. Kesteven related a case of Paraplegia, caused by Traumatic Hæmatoma, in the Dorsal Region. In this case there had been some pre-existent disease, which had caused the spontaneous removal of the body of the seventh dorsal vertebra. About three months before death occurred the patient had received a blow on the back, which had caused some displacement at the diseased part and rupture of some bloodvessels, thus giving rise to an effusion of blood into the spinal canal, and consequent pressure on the cord. Some of the blood had also escaped anteriorly, forming a hard tumour in the posterior mediastinum, which had pushed forward the sympathetic ganglia and caused destruction of the rami communicantes of the seventh ganglion on each side. The heads of the seventh and eighth ribs on each side were also diseased. The narrator of the case gave an account of the symptoms produced, and pointed out the effects produced by the pressure on the cord, and by the damage caused to the sympathetic nervous system. Mr. Roger Williams said the case was interesting as an example of cure of spinal caries without supuration. It showed, too, that paralysis was produced by the tumour pressing upon the spinal cord. He thought it might be also an example of what Sir James Paget had called "residual abscess."—Dr. Horrocks observed that this was the first case on record in which ankle clonus had not been associated with degeneration of the lateral columns of the cord; although clonus had been present for a few seconds after a fit from temporary exhaustion of the lateral columns.—Mr. Butlin asked if the blood-clot had been examined microscopically, as it looked like a blood-cyst or hæmorrhagic sarcoma. There was no trace of suppuration, and the history pointed rather to a tumour than to hæmorrhage.—Dr. Kesteven replied that it had not been examined microscopically.—Dr. Wilks supposed Dr. Horrocks did not mean that the excess of spinal reflexes was directly produced by lateral sclerosis. He thought it was due to excitation of the grey nervous matter within the degenerated cord.

Dr. Hadden described a case of Disseminated Sarcoma. The patient was a gentleman, aged thirty-eight, in St. Thomas's Home. Shortly before admission he had been operated on for fistula in ano. On admission, he was dull and drowsy; this increased; then cedema of the legs came on; the pulse became very small and frequent. Temperature reached only 101.2°. No optic neuritis, nor evidence of organic disease during life. He died comatose. Post-mortem: The pericardium on each surface was studded with small new growths; similar growths were seen in the muscular substance of the heart, parietal layer of pleura, both surfaces of diaphragm, omentum, mesentery, liver, and spleen. The right kidney was remarkable, the capsule was studded with numerous white masses of calcareous matter. Several small bodies like tubercles were seen on the arachnoid, which were found to be only thickenings of the membrane; no

glands enlarged. The tumours were round-celled sarcomata. In the heart the cells were round; matrix amorphous, in some places alveolar. In the liver the growth was interlobular. Beneath the capsule of the right kidney was an extensive infiltration of round cells, which sank down between the tubules. The case during life was thought likely to be acute tuberculosis, and was also very interesting, as the symptoms were acute, lasting only a fortnight.—Dr. Norman Moore asked if the new growth on the kidney was the same in character as that in the heart; and whether Dr. Hadden was sure the growths were sarcomatous. The indurations on the kidney were like those common on the liver. He thought that in the heart sarcomata were nearly invariably pigmented.—Mr. Butlin had examined these specimens carefully, and was not prepared to affirm that the growths were sarcoma growths if this would be in opposition to the general characters of the disease. It was extremely difficult to distinguish such round-celled sarcomata from tubercular deposits or other round-celled formations.—Dr. Bedford Fenwick remarked on the paroxysmal character of the pain associated with new growths in the heart.—Dr. Hadden replied that the growth in the right kidney in the main resembled that elsewhere. He had never seen any growth quite like it, and he thought it unique. He did not know whether there was paroxysmal pain in the region of the heart.

Mr. Malcolm Morris showed a living specimen of a very rare skin disease which he called *Xanthoma Tuberosum*. The patient was a married man, aged forty-eight, who was suffering from saccharine diabetes. There was no history of syphilis or rheumatism; no jaundice or evidence of disease of the liver. He complained of sleeping badly, and of dimness of sight with occasional mists before his eyes. There was distinct anæsthesia of the soles. Heart weak; reflexes normal. The eruption appeared suddenly, first on the outer side of the thigh, then spreading to the trunk, to between the fingers, and on the mucous membrane of the mouth. It consisted of small rounded firm pink tubercles, with depressed centres which had more of a fawn-color in the centre. Many of the papules had disappeared since the case first came under his care. With the patient's consent he removed one of the growths and examined it microscopically. This showed small nodules in the corium, with a delicate fibrous intercellular matrix; towards the centre the fibrous tissue became more compact and firm. The superficial epithelial cells were normal. There was no connection with any glandular structures, and the older papules contained no blood-vessels. In one place he found a collection of round cells about a vessel, and he suggested whether this might not be the real origin of the growths—the tissue ultimately contracting and so causing degeneration of the cells. This case differed from those of *xanthelasma* in many respects, chiefly in its association with diabetes and not with jaundice; the sudden onset of the rash, and its rather rapid disappearance, and in the fact that the eyelids were not implicated. But on the other hand it closely resembled two cases, one of which had been recorded by Drs. Gull and Addison, the other by Dr. Britton. The three cases were all in men; they all had diabetes, they all affected the same locality and avoided the same parts; in all the rash appeared suddenly, and gradually, but rather rapidly, disappeared. To these exceedingly rare cases the name of *xanthoma tuberosum* had been applied.—Mr. Morratt Baker said the case was of great rarity, but it differed so much from *xanthelasma* that he doubted whether it should have that name at all. Dr. Duckworth said that the case did not re-

semble xanthelasma and ought not to be called by that name. Its actual appearance did not justify the use of the term applied to it. Dr. Radcliffe Crocker said in xanthoma the nodules were always soft and yellow, but these were firm and not yellow. The rapid appearance and disappearance of the rash quite separated it from true xanthoma. In xanthoma there were, also, stellate fat cells and oil globules.—Dr. Morris said the rash was chamois-leather colored in the centre and pink in the centre. There was an absence of the oil globules in ordinary xanthelasma; microscopically it was more like keloid or fibroma, but it was exactly like the cases described early by Drs. Addison and Gull as xanthoma tuberosum. The case was referred to the Committee appointed last year to investigate xanthelasma.—Dr. Morrison compared this rash with the eruption common in gout, and said it was also similar to molluscum. He thought in all such cases the parts affected first were the hair-follicles and sebaceous glands.

Dr. Robert Barnes showed a specimen of Pigmentation of the Cervix Uteri. It consisted of the vaginal portion of a uterus affected with hypertrophy, and which projected from the vulva. It was pigmented on the surface. The patient was a Hindoo. The parts not exposed were of the normal rose color. Dr. Ewart had examined the part microscopically, and found the pigmented surface to have the leading characteristics of healthy skin; the horny layer was thin; rete Malpighii well furnished with closely-packed cells, like those of the skin; the deep vertical cells were deeply pigmented; papillæ projected forwards into the epithelium, and contained vessels of new formation. In the unpigmented part corium was absent, the rete abutting upon the firm muscular tissue of the uterus. The pigment consisted of fine granules, and was present in the nuclei of the cells. There was thus evidence of a further change than one of dying of the exposed surface of mucous membranes. It was new to him, but probably familiar to practitioners in India.—Dr. Wilks said that pigmentation was a very difficult subject, for in some cases it was due to local causes, and in others to deep constitutional changes, as in Addison's disease. Professor Laycock thought that pigmentation of the face was always associated with disease of the genital organs.

Dr. Norman Moore read a paper on Lung with Impacted Foreign body. The right lung of a child, aged twelve, who died of typhoid fever. The lung is partly collapsed, and in its lowest lobe are several reddened patches. In one of these, near the pleural surface, was fixed a spicule of bone three-quarters of an inch long. The spicule, which looks like the neural spine of a fish vertebra, had one end in a minute bronchus, the wall of which it had penetrated. Four years ago the child was suddenly seized with pleurisy. It was tapped in St. Bartholomew's Hospital, pus was let out, and as the wound continued to discharge a drainage-tube was put in. The child attended with this as an out-patient, and at length the wound was closed. The scar was distinct. The lung was firmly adherent to the chest-wall. The spicule of bone passing deep into the lung probably set up pneumonia, which was followed by the empyema four years ago. The empyema was emptied, and the bone remained, a very exceptional circumstance. The typhoid fever, of which the girl died, was remarkable in the large extent of intestine affected, and in the fact that the middle part of the vermiform appendix was externally tumid and internally ulcerated all round. Perforation of the vermiform appendix had occasionally been a cause of death in typhoid fever, and had been thought a condition, preceding the fever. In this case, and

in another post-mortem which he had lately made, the ulceration of the vermiform appendix was clearly one of the results of the typhoid fever. A further point of interest was that in the middle of the epiglottis there was a small ulcer.—Dr. Goodhart said that foreign bodies more commonly caused lung disease than was generally suspected; he had made two autopsies quite close together of cases of obscure lung disease, in each of which he discovered the cause of the mischief in a foreign body.—Dr. MacLagan said that in cases of foreign body in the lung there was fetid expectoration of a peculiar odor. Dr. Begbie had particularly pointed this out, and had been able to diagnose the source of a troublesome cough and expectoration by this means; he also found that turpentine given internally removed the fetor, and rendered the patient more comfortable.—Dr. Sharkey said that it was not necessary to suppose that the foreign body had actually passed through the lung, and so caused the pleurisy, for in cases of obstruction of a bronchus by an aneurism, lobular pneumonia and pleurisy were often met with. He had under his care a patient with a tooth in a bronchus, causing partial obstruction, and he got an attack of pleurisy, although the tooth was still in the bronchus.

Mr. Eve showed a specimen of Malformation of a Lamb. All the parts developed from the first visceral arch were absent on one side; the superior and inferior maxillary bones and palate bones were absent; the temporal bone was dwarfed, and there was no trace of the ossicles of the ear. The brain and cranial nerves were normal, except that the fifth and ninth nerves were smaller on the right (the deformed) side. He had not been able to examine the arteries. He could not find any similar case, although absence of the lower jaw was tolerably common in lambs. Possibly, the cause of the deformity was some vascular lesion, as thrombosis of the internal maxillary artery.

The following card-specimens were shown:—Congenital Malformation of Skull, by Mr. F. Treves; Double Hydrosalpinx, by Dr. Norman Moore.

The ordinary meeting of this Society was held on November 21st, Dr. George Buchanan in the chair. He presented the new volume of the Transactions to the Society, and also announced that in April next there would be a discussion on the pathological condition of the various organs in diabetes.

Dr. Horrocks showed a living case of Bromide of Potassium Rash in a girl aged ten years, who had been taking twenty-five grain doses of bromide of potassium twice daily for four months; one month ago red swellings like erythema nodosum appeared over the tibiae, and a week later pustular points were present on the swellings, and coalesced; shortly afterward it came upon the extensor aspect of the arms and forearms; there was no rash elsewhere. The rash was now undergoing involution and was not so characteristic as it had been. Dr. Horrocks alluded to the absence of the rash in the usual acne situations and thought it was rare to find it on the extensor aspects of the limbs only.

Dr. Thin considered that these cases presented sufficiently characteristic features for them to be diagnosed independently of the history and alluded to a case in which he had done so. His microscopical investigations in a case of iodine rash led him to consider that the condition was not due to inflammation of the sebaceous glands and therefore not a true acne, but that it was due to the drug affecting directly the walls of the vessels, producing stasis and its consequences.—Dr. Radcliffe Crocker said that the presence of the rash upon the extensor surfaces was not so rare as Dr.

Horrocks seemed to think; several cases had been shown by Dr. Barlow, himself, and others, with the rash in these positions, and he described a case now under his care at the East London Children's Hospital of a girl aged nine, who, after taking ten-grain doses of bromide for a week, showed the characteristic pustules upon the anterior surfaces of the legs and on the arms and chest; the drug was not stopped, on account of the fits from which she suffered, but some arsenic was given; the following week superficial abscesses two inches in diameter were present on the site of many of the pustules. The patient had been half starved.

Dr. Hoggan showed and described microscopical specimens of Multiple Lymphatic Nævi of the Skin. He considered that the condition was a common one, though hitherto unrecognized, and that it was probably the early stage, or predisposing cause of many other diseases connected with the lymphatic system, such as elephantiasis, lymphangioma, etc. It differed from the case of lymphangiectodes presented to the Society by Drs. Tilbury and Calcott Fox, as that had no navoid development of lymphatics, and also from Hebra's case of lymphangioma tuberosum multiplex, which, both from the drawings and description, he thought was not a lymphatic disease at all. His patient was a boy, aged nine years; the nævi were of the size of a split pea, flattened, and of a transparent pale-lilac tint, and were situated upon the right leg and ankle, which had been repeatedly attacked by an erysipelatous inflammation, causing great pain and slight thickening of the ankle; in short, the symptoms of the early stage of elephantiasis Arabum. The epidermis was infiltrated with the branched cells of Langerhaus. The abnormal lymphatics traversed the whole thickness of the dermis below, but above did not extend higher than the normal lymphatics, nor nearer than usual to the hair-follicles or sweat glands. There was nothing abnormal in the structure of the lymphatics individually, and the fact that none of the nitrate of silver injection had been extravasated showed that they were actually walled tubes. He thought the disease was an early and curable stage of elephantiasis cruris.—Dr. Pye Smith asked if the affection was congenital.—Dr. Thin endorsed Dr. Hoggan's opinions as to the structure of the tumours, but doubted their relationship to elephantiasis Arabum, as there was none of the imperfect fibrous tissue seen in that disease. He thought the case corresponded with one described and figured by a Russian observer in the *Archiv für Dermatologie* a few years ago.—Dr. Hoggan replied that it was in a stage before the development of fibrous tissue; and with regard to its being congenital, thought that it was, but the history was defective on that point.

Dr. Samuel West showed and described a specimen of Sarcoma of the Bladder and Prostate. The patient was a man aged twenty-one, and showed no symptoms of disease until a month before death, when he had retention of urine; no trace of a tumour could be felt by the rectum. A few days later hæmaturia, followed by retention, occurred, and the catheter had to be used; the hæmorrhage continued to be profuse, and he died of exhaustion. Post-mortem in the position of the prostate was a tumour nearly as large as the bladder, and in the bladder were several polypoid tumours, the largest rather larger than a Tangerine orange; one was in the trigone, and another projected into and blocked up the dilated urethra; signs of hæmorrhage were present in it, and doubtless it was the source of the bleeding and cause of the retention. The tumours were split up but not villous; section of the prostate tumour showed it to be a soft, round, and spindle-celled sarcoma. There

were no secondary growths, the kidneys were studded with small abscesses, and the ureters and pelvis dilated, the bladder being hypertrophied, which was good evidence that though there were no symptoms until a month before his death, the tumours were present for a longer period. The delay in the development of symptoms reminded him of the case of mediastinal tumour that he had showed, in which there were no symptoms until two months before death.—Mr. Roger Williams said that growths like this were much more common in elderly people. The practical point was, Were these growths infective? Evidently these were not, and he compared them to those medullary growths of the bladder and rectum which were often non-infective. He then showed his museum specimen, which had no history attached to it, of a small tongue-like growth at the neck of the bladder, which had belonged to a boy; the bladder was hypertrophied.—Mr. Barker mentioned several cases of tumours of the bladder, in all of which he had noticed this feature in common—namely, that the growths were more or less polypoid, whether they were cancers or sarcomas.

Dr. Henderson showed a Heart with Syphilitic Gummata in the Wall of the Left Ventricle, and microscopical specimens in illustration of it. A man, aged thirty, was brought in a moribund condition to St. Mary's Hospital, and died in a few minutes. It was stated that he had seemed well until a fortnight before his death, when he began to complain of faintness and pain in the præcordial region. On his way to his work he suddenly staggered and fell, groaned, put his hand to his heart, and was unconscious from that moment to his death. At the post-mortem examination the only organ affected was the spleen, which weighed twelve ounces; it was congested, firm, and adhered to the parietes. The liver weighed sixty-two ounces, and had a depressed fibroid scar in the right lobe, but was otherwise normal. The heart weighed thirteen and a half ounces. The pericardium over the left ventricle was studded with pale yellowish-white, slightly projecting elevations, and one or two were over the right ventricle. The endocardium of the anterior wall of the left ventricle was studded with similar nodules. On cutting into the septum a mass of fibroid tissue, a quarter of an inch thick and one and a half inches long, and two inches broad, was seen extending into the muscular substance, with which it gradually blended. Microscopically the muscular substance was permeated by tissue, with gummatus characters, but there was no sign of caseous spots, or of fatty degeneration in the muscle fibres. The lumen of the smaller vessels was narrowed by thickening of the intima. He thought that the appearances of this case made it a connecting link between the cases of fibroid degeneration of the heart described by Dr. Hilton Fagge in vol. xxv. of the *Transactions*, and those of Dr. Burney Yeo in vol. xxvi. There was no history of anginal attacks, and the larger coronary vessels were not blocked in any way; the question arose whether the blocking of the lumen of many small vessels would have a similar effect to the occlusion of the larger vessels, and so cause sudden cessation of the heart's action.

Mr. Roger Williams then showed a wax model of a case of Testis in Perineo and Congenital Hernia. Before admission into the hospital there were great pain and tenderness over the tumour on the right side of the scrotum; an ounce of straw-colored fluid was drawn off by the aspirator, and on taxis the hernia was reduced. The testicle was swollen and tender, and could be felt in the perineum. This position of the testicle occurred seven-

teen times out of twenty-two cases on the right side, and congenital hernia was rarely associated.

Mr. J. B. Sutton showed the Skeleton of a Baboon affected with Rickets; it was admitted into the Zoological Gardens when two months old, fed on fruits and nuts instead of milk, and died in four months. The viscera were not preserved, but the skeleton showed decided signs of rickets. The epiphysal cartilages were enlarged; that of the femur was ten millimetres instead of one. There were three layers: 1. Normal cartilage. 2. Longitudinal rows of cells. 3. Imperfect ossification enclosing cartilage cells. The tibiae were bowed and very soft. The periosteum thick and succulent. The skull was six millimetres thick, soft and spongy. In another specimen that he found in the museum the skull was twelve millimetres thick. In answer to Dr. Buchanan, he said that dentition was not affected.

Dr. Hadden showed Microscopical Sections of the Cord in Canine Chorea, in which disease there are rapid contractions of the muscles, as if under the influence of the interrupted current, the disease resembled spasmodic torticollis more than human chorea; it generally followed distemper, and was fatal. Like the cases described by Drs. Gowers and Sankey, there were masses of leucocytes scattered irregularly through the cord, but while in their cases these cells were in the white matter, in his they were among the grey matter, distended capillaries could easily be seen. The appearances were suggestive of an early stage of disseminated sclerosis, and, as they were not constant, were probably secondary, perhaps due to over-action.

Dr. Pye Smith showed the fresh organs in a case of Colloid Cancer in a man aged sixty years. His first symptoms were cough and pain in the leg, but there was no tumour felt; but later on a small tumour was detected in the region of the liver, and he had pain in the course of the sciatic nerve, and the diagnosis of retro-peritoneal cancer was made. There was no vomiting or hæmatemesis. Post mortem there was no cancer of the liver, but it was simulated by a part of the retro-peritoneal tumour. A very large cancer affected the posterior wall of the stomach, projecting into it, but united to the cancer behind; another tumour projected into the duodenum. There were a few secondary nodules in the liver, while the lung was studded with pea-sized nodules. The microscopical characters were those of colloid cancer, the paucity of vessels accounting for the absence of hæmorrhage during life.

Dr. Frederick Taylor showed the Heart in a case of Ulcerative Endocarditis. A man, aged twenty-six, had had rheumatic fever, at the age of fifteen, with some cardiac complication. Five months ago he had shortness of breath and wasted. For the last six weeks he had had œdema of the feet. When admitted he had general anasarca, and looked as if suffering from renal disease. There was marked pyrexia and a double aortic murmur, tenderness over the spleen, and the urine was abundant and highly albuminous. Ulcerative endocarditis was diagnosed. Post mortem both aortic and mitral valves were affected with old and recent disease—viz., induration and ulceration. The left ventricle was dilated and hypertrophied. The spleen had several embolic infarcts. The kidneys showed cloudy swelling, and the capsule was slightly adherent in one part. The question was whether the kidney affection was primary or dependent upon the endocarditis? Dr. Taylor thought it was due to the endocarditis, as similar conditions had been observed in other cases.

The card specimens were Thrombus in the Left Common Iliac, by Dr. Kingston Fowler, and

Congenital Malformation of the Heart, by Dr. Turner.

Acute Dilatation of Stomach.—Osteitis Deformans.—Malformed Heart.—Rachitic Osteomalacia.—Stricture of the Intestine.—Malformation of Auricle.—Symmetrical Gangrene.—Cancer of Œsophagus.—Noisy Respiration.

The ordinary meeting of this Society was held on December 5th, the President, Dr. Wilks, in the chair. Several specimens, and a case of special interest were shown—namely, a case of extreme rachitic osteomalacia by Mr. Barwell, which at the suggestion of Mr. R. W. Parker, was referred to the Rickets Committee. The body of a child who had died with symmetrical gangrene of the extremities was exhibited by Dr. Southey, and the larynx of a child with folding of the epiglottis producing a peculiar form of dyspnoea by Dr. Lees.

Mr. Henry Morris showed the Stomach of a man which was in a condition of acute dilatation, and gave the following account of the case:—The patient, aged thirty-seven, was admitted into the Middlesex Hospital for suppurative of the ankle-joint. An operation having been determined on, on November 11th ether was given for about half a dozen respirations, and afterwards chloroform for about a quarter of an hour. For the following two days he vomited excessively a thin greenish fluid; the longest interval between the acts of vomiting was never more than one hour. He had taken a mixture of chloroform and ether on a former occasion without ill results. He had been prepared for the anæsthetic by being given a dose of house mixture, and an enema; a light breakfast was taken early. After the anæsthetic, orthopnoea became marked, the temperature fell below normal, the quantity of urine decreased, until towards the end none was passed; the pulse was weak and rapid, and the skin was cold. Death was due to exhaustion. At the necropsy, the stomach measured $7 \times 12 \times 4$ inches, and reached almost to the symphysis pubis; it contained twenty-eight ounces of fluid. The coats of the stomach were thin, and contracted when cut; the kidneys were contracted and scarred on the surface, and one contained a cyst. In the upper lobe of each lung was a cavity, and the lungs contained miliary tubercle. The vomiting was unlike that seen after chloroform, and there was no intestinal obstruction. Mr. Morris referred to a few other cases of a similar kind on record, where excessive vomiting occurred in patients with a similar condition of the kidneys; but all the other cases were much more chronic in their course, with the exception of three reported by Dr. Hilton Fagge. Mr. Morris was inclined to attribute the dilatation of the stomach to the large quantity of gastric fluid secreted, this over-secretion being brought about by nervous influence. He, therefore, thought that the term acute dilatation of the stomach was not a good one to describe the condition, and suggested the word gastrorrhœa. Cohnheim had suggested that in cholera there might be such an influx into the intestines from some nervous influences.—Dr. Goodhart gave a few notes of the post-mortems of five cases of acute dilatation of the stomach, which had occurred at Guy's Hospital since 1875, and which to some extent corroborated Mr. Morris's theory of the nerve origin. Of these cases, four out of the five involved the peritoneum, and the remaining one the sympathetic. Case 1 was a man, aged twenty-two, with strangulated inguinal hernia and suppurative peritonitis. Case 2. A female, aged forty-eight, with a growth in the neck pressing upon the veins, left vagus, and sympathetic. Case 3. A female,

aged forty-nine, with ulcerating colon, acute enteritis, and thrombus of the superior mesenteric artery. Case 4. A female, aged twenty-four; amputation at hip-joint, suppuration in other joints, and caseous glands in the lumbar region. Case 5. A female, aged thirty-four; death nine days after ovariectomy; stomach symptoms began two days after operation. There was great flatulent distension on the fourth day; constant vomiting ensued on the sixth day. Post mortem there was very little peritonitis and thrombus in the iliac veins.—Dr. Pye-Smith said that Dr. Lauder Brunton had preceded Cohnheim in the enunciation of the theory of the relation of nerve paralysis to the profuse evacuations in cholera; and Dr. Pye-Smith had read a paper on the subject, in conjunction with Dr. Brunton, at one of the meetings of the British Medical Association; he would be glad to know from Mr. Morris whether there had been any analysis of the vomited fluid.—Dr. Mahomed wished to know the condition of the kidneys, as he had met with two cases of lardaceous disease of the kidneys, in which there was a large amount of fluid ejected from the stomach.—Dr. Payne alluded to two specimens in St. Thomas's Hospital Museum, where during life a diagnosis of intestinal obstruction had been made; but post mortem there was great distension of the intestine, but no obstruction; they seemed analogous to these cases of dilatation of the stomach. With regard to the influence of chloroform, while he thought that it might account for the symptoms by inducing paralysis of the muscular walls, it appeared to him very doubtful whether the distension could be produced by the quantity of fluid in the viscus.—Dr. Wilks remarked that while they had only a few fatal cases on record it was not improbable that there were less severe cases which recovered due to similar causes, and that the severe gastric symptoms which sometimes occurred in gouty people were possibly of this nature. Mr. Morris, in reply to Dr. Mahomed, said that the kidneys were indurated and scarred, and one had a cyst, but that there was no lardaceous disease. He regretted that there had been no analysis of the fluid, but the true nature of the case had not been diagnosed. Alluding to the remarks of Dr. Payne, he did not suppose that the dilatation occurred until the stomach was worn out with the incessant vomiting, and so allowed of accumulation of the fluid.

Mr. Morris then showed photographs of a case of Osteitis Deformans. The disease had been present for about twelve years, and had begun in the left leg. The legs and thighs, the patella, the ribs, the vertebrae, the clavicles, and, to a slight extent, the cranial bones were affected. The lower extremities of the tibiae, the fibulae, the feet, and the lower jaw were not affected in this case. His general health was good, but he had a mitral murmur, and the urine contained less than the normal quantity of urea.—Mr. Treves said that the case was a further illustration of two facts:—1. That the bones of the arms were usually free. 2. That all cases where the bones of the upper extremity, except the clavicle, were involved, occurred in women. The loss of stature might be accounted for partly by the curves of the spine, and partly by its subsidence in a vertical direction. Finally, Sir James Paget has ascribed the condition to an inflammatory affection of the bone, and, comparing it with other inflammations of bone, Mr. Treves said that in the case of a girl aged fifteen years, under his care with chronic periostitis from congenital syphilis, the deformity in the leg presented precisely similar characters.—Mr. Noble Smith asked if any treatment had been attempted; in all Sir James Paget's cases iodide of potassium had been given with either no effect, or a bad one;

he had, therefore, in a case now under his care, attributed the disease to some defect of nutrition, and treatment in accordance with that view had benefited the patient. The deformities were exactly like Sir James Paget's description, and were largely due, he thought, to the weight of the body. There was a family history of gout, cancer, and phthisis; but the general health of the patient was good.—Dr. Wilks said that one of the first cases ever shown was a man under his own care, who had previously been under a great number of medical men, and had a pile of prescriptions from them, and the main ingredient was the same in all—namely, iodide of potassium. He thought it was a common error to suppose that iodide of potassium had any influence on fully-formed bone.

Dr. Turner then showed a Congenitally Malformed Heart. The organ consisted of an auricle with two appendices, the left being small, and a ventricle with an auriculo-ventricular valve of tricuspid form. The auricle received the inferior vena cava, and a right and a left superior vena cava. The pulmonary veins communicated with the left superior vena cava. The opening of the coronary sinus was close to that of the inferior vena cava. There was a well-marked Eustachian valve, and a narrow crescentic membranous fold over the entrance to the left auricular appendix, the rudiment of an inter-auricular septum. The aorta arose from the front of the ventricle, and gave off the coronary arteries and the three vessels from the arch in the usual order, and supplied the pulmonary circulation through an open ductus arteriosus. The arch of the aorta was directed to the right over the root of the right lung. Behind the aorta was a fibrous cord passing to the pulmonary arterial vessels representing the closed pulmonary artery. There was what appeared to be a rudimentary left ventricle without any trace of a left auriculo-ventricular opening. The specimen was obtained from a male infant, aged fifteen months, who was brought to the out-patient department at the North Eastern Hospital for Children for bronchitis. Only a slight degree of cyanosis was observed until shortly before it died. The child had been born at full time, and was well nourished, and seemed healthy then, but had not thriven. The cyanosis had not been observed by the friends. The mother had no illness during the pregnancy, and gave no history of rheumatism beyond slight rheumatic pains occasionally.

Mr. Barwell then read an account of his case of so-called Rachitic Osteomalacia, with extreme Deformity. The patient was a female, aged seventeen years, who had been under Mr. Barwell's care for the last three years, and the deformity had improved very slightly. The patient comes from the potteries in Staffordshire, is of healthy parentage, and the brother is a tall, well-built man. Mentally she is juvenile rather than weak-minded, and is as yet non-pubic. Nearly every bone presents extreme deformity, but the humeri, right tibia, and left ulna are bent to most acute angles; in the ulna the olecranon is elongated and bent at a right angle to the shaft. She is quite unable to stand. The bones are remarkably brittle, though rather less so than they were, consequently she has fractured the bones of both upper and lower extremities several times. There is no beading of the ribs nor enlargement of the epiphyses. Mr. Barwell's experience led him to consider the bones to be of normal thickness, but soft from deficiency of lime salts, and he questioned whether these extreme deformities were ever produced by true rickets. Some years ago in attempting to improve the deformity of the femur of a boy in a similar condition to this patient the chisel went through the bone with very slight resistance, and about five

ounces of pure oil flowed out. Both these cases suffered from pains at the convex parts of the bones. Mr. Barwell thought that these extreme distortions arose from increase of the medulla, at the expense of the bone substance, the so-called eccentric atrophy, while there was very little bone-earth deposited in the thin shell of bone round the medulla.

Dr. Norman Moore described his specimen of Stricture of the Intestine at the Ileo-cæcal Valve, from a man in whom colotomy had been performed in the right lumbar region. The wound showed no unhealthy suppuration. The intestines above and below contained a considerable quantity of soft fluid fæces, but were not greatly distended. The stomach was normal. The small intestine was dilated, oedematous, and reddened; three and a half inches above the valve it showed extensive irregular ulceration, which extended all round; some of the ulcers seemed healing, and there were puckering as of healed ulcers. The ridge of the ileo-cæcal valve was very low, and the orifice was so contracted as but just to admit a large probe. Below the valve, for three inches, there was a less degree of ulceration. The colotomy wound was two inches below the valve in the large intestine. No tubercle was discoverable. Mesenteric glands normal. Externally the intestine was not abnormal, except that the lowest part of the ileum was slightly adherent to the abdominal wall. The intestinal wall was thickened above and below the stricture. No enlarged glands were found; the rectum and all the muscles and bones were normal. Microscopic examination showed that the stricture is associated with a new growth, consisting of abundant round cells penetrating all the structures of the intestinal wall. The patient was a man, aged forty-seven years, who died under the care of Dr. Andrew, in St. Bartholomew's Hospital. An attack, the first, of obstruction of the bowels, began on Oct. 18th. The bowels not having acted up to November 1st, on that day colotomy was done by Mr. Marsh. At the time there was no relief; but the next day a large quantity of fæces came through the wound. The patient died on November 4th. A microscopic section of the tissue of the stricture was exhibited.—Dr. Norman Moore also showed a specimen of Malformation of the Right Auricle. It was the heart of a woman aged thirty-three years. All the cavities are somewhat hypertrophied and dilated. The aortic valves are incompetent and thickened. The cords and edge of the mitral valve are thickened, and the flaps adherent to one another. The edge of the tricuspid and some of its cords are slightly thickened. There was considerable narrowing of the mitral orifice and a slight degree of tricuspid stenosis. The left auricle is very capacious, and its endocardium is much thickened and puckered in several parts. The septum of the auricles is complete, and the fossa ovalis less distinct than usual. The part of the right auricle near the septum is divided into two by an oblique transverse partition. This partition is of the same structure as the walls of the auricle. Its anterior half is twice as thick as its posterior. It stretches one inch into the auricle; it begins just below the fossa ovalis and stretches from the septum of the auricles near the orifice of the inferior vena cava ending on the posterior wall of the auricle. The valve of the coronary sinus is of the usual form, and may be seen beneath, and quite free from, this projection. In the middle of the free edge of the projection is a thickening one-quarter of an inch long, and the free edge is rounded and slightly thicker than the main part. The origin from the auricular wall is thicker still. He had seen one other example of this variety. It is probably developed in

connection with the Eustachian valve. Another specimen shown by him, with microscopic sections, was Tubercle of the Liver, belonging to a man, aged forty-nine, who died in St. Bartholomew's, under the care of Dr. Andrew, of tubercular pulmonary phthisis with ulceration of the larynx. The liver is studded throughout its substance with numerous whitish growths, most of them of the size of a large pin-head. Microscopic sections show that these are tubercles. Giant cells may be found in most of them. In some the cellular elements are not at all degenerate; in others caseation has taken place; all show a considerable amount of connective tissue. Virchow, Cornil and Ranvier, and Rindfleisch describe tubercle as often found in the liver in the general tuberculosis of children; and Virchow states that it more often occurs in the liver than is generally thought; but cases in which the whole liver is infiltrated at so late an age as forty-nine in phthisis, with cavities in the lungs, are certainly rare in London.—A fourth specimen was the Elbow Joint from a case of Scarlet Fever. The joint shows thickening of the synovial membrane, with roughness in two places and one narrow adhesion. When opened it was full of pus. The terminal joint of the right index-finger and the right elbow were similarly affected. No abscesses were found in the body or head. There was some pericarditis and general peritonitis. There were some minute growths on the mitral valve, and in the lower lobe of the left lung there was a small pneumonic patch. In each kidney was an infarction, broken down so as to form a small abscess. The patient was a girl, aged six years, who died in St. Bartholomew's Hospital, under the care of Dr. Gee. Another child of the family had died of scarlet fever. This one was taken ill on Sept. 28th. On Oct. 10th she had rheumatic symptoms, which rapidly grew worse. On admission, on Oct. 19th, both elbow-joints were found to be much swollen. The temperature was 100° on admission, and twice rose to 104°·9°. The child grew weaker, and died on Oct. 23rd. The case is of interest in its bearing on the question of the pyæmic or non-pyæmic nature of scarlatinal rheumatism. This case, in its anatomical features, was clearly pyæmic.

Dr. Mahomed protested against a case like this of pyæmic inflammation of a joint, after scarlet fever, being regarded as in any way of the same nature, or throwing any light upon scarlatinal rheumatism. These pyæmic cases were very rare, while scarlatinal rheumatism was very common. In their clinical aspects they resembled acute rheumatism and yielded to salicylates; but, as a rule, they were of a milder type than ordinary acute rheumatism. There were some septicæmic cases, but they also were rare, and had no joint troubles; he thought that it was very misleading to represent scarlatinal rheumatism as not amenable to treatment.—Dr. Wilks asked if the pyæmia could be traced to any local cause, such as an abrasion of the throat.—Dr. Moore had examined carefully, but found no local abrasion, he had shown the case from a morbid anatomy point of view, and he had experienced some difficulty in drawing a line at the point where rheumatic affections end and pyæmic symptoms begin.—Dr. Barwell said he had always assumed that absorption of morbid products, analogous to what occurs in gonorrhœal rheumatism, was the cause of the joint inflammation, and had always entertained the idea that scarlatinal rheumatism was not true rheumatism.

Dr. Southey brought the body of a child two and a half years old who had died with Symmetrical Gangrene. She was of healthy parentage, and had been previously quite healthy, except that two or three months ago she had a febrile

attack with some purpuric spots. On Friday, December 1st, she had a pain in the head; on the following morning she seemed quite well again, but in the afternoon complained that she had hurt her leg, but when her father rubbed it she said that it pained her, and he then noticed some lividity over the calf. Soon after she was sick, febrile, and complained of headache; at six p.m. she was worse, and the lividity of the calves had extended both upwards and downwards; in the night the backs of the arms were observed to be affected, and at about six a.m. patches formed upon the buttocks. She was admitted into St. Bartholomew's Hospital at noon of December 3rd, looking moribund; the pulse was rapid and feeble. The tibial arteries could not be felt; the lungs and heart were normal; at six p.m. she had taken some nourishment; she was ordered a warm bath and some nitro-glycerine; the cheeks were beginning to show a slightly livid redness. At seven p.m. convulsions came on and continued until she died at midnight, thirty-two hours after the first symptoms. Renaud had described similar cases, and Dr. Southey had met with two or three others; Dr. Moore had cut up the left femoral and tibial arteries, but no embolus or other obstruction could be found. The theory advanced has been that there is spasm of the arteries, and then migration of blood elements into the skin, for the gangrene was quite superficial.—Dr. Norman Moore said that he had examined the blood microscopically, and that it was whitish comparatively, containing many fat globules, something like the so-called "raspberry-juice blood" found in some cases of diabetes.—Dr. Wilks mentioned a case of this kind in which hæmatinuria was present.—Dr. Southey had also observed intermittent hæmatinuria in a case with symmetrical gangrene of the fingers. In his present case only an ounce of urine could be obtained, and it contained some albumen.

Mr. Eve brought a recent specimen of Cancer of the Oesophagus; leading from it were two fistulous passages into a cavity of the right lung, which, had no definite wall. The patient had suffered from dysphagia for six months, and was in the hospital for only two days before death. Bougies were passed, and gave relief, but no attempt was made to administer food by the mouth. In the same patient an abnormal condition of the colon was found; from the cæcum the ascending colon passed down almost to the pubes, and then curved upwards towards the right kidney. He also showed the calvaria of a man who had died an hour and a half after a blow on the head; the skull was fractured, the fissure extending across the course of the middle meningeal artery, which lay in a very deep groove in the bone; the dura mater beneath this was separated from the bone by a large blood-clot.

Dr. Lees exhibited the Larynx of an infant, aged twelve months, which had, during its whole life, manifested a peculiar noisy respiration. The condition found threw light upon a set of cases of rare occurrence, but of considerable interest. An infant, almost invariably of the female sex, suffers from the moment of its birth from a noisy inspiration, expiration being much less affected or entirely free, and the cry-sound being quite clear. The noise made during inspiration is often loud and harsh; it is of lower pitch than the crow of laryngismus. It continues, though it is not so loud, during sleep and after the administration of chloroform. There is usually some recession above the sternum, and slightly at the base of the thorax; but not much, and generally sufficient air enters the lungs. In some cases exacerbations have been brought on by exposure of the surface to cold (when the chest was stripped), by flatulence, and

other causes; but as a rule the condition is fairly constant. Perfect recovery ordinarily occurs after the lapse of a year or more. In this case the child died of insidious diphtheria. About a month ago a laryngoscopic examination was made, and it was then seen that the epiglottis was folded on itself like a leaf on its mid-rib, the ary-epiglottic folds being thus brought close together, and the superior orifice of the larynx converted into a linear median slit of very small diameter. This condition was found post-mortem to be actually present, the ary-epiglottic folds being almost in contact. Above them, below the centre of the folded epiglottis, was an opening of the size of a pinhole, and between the arytenoids a second opening a little larger. The trachea was lined with diphtheritic membrane. The peculiar breathing thus appears to be due to a congenital abnormality in the epiglottis. This was the fourth case which Dr. Lees had seen. Similar cases have been observed by Dr. Gee and by Dr. Barlow, but they have not yet been published, and Dr. Lees believed that this was the first post-mortem examination which had been obtained, and also the first time that the cause of the obstruction had been ascertained during life.

Dr. Finlay and Mr. Barker were then appointed auditors for the year, and the meeting adjourned.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

The Endemic Hæmaturia of the South-east Coast of Africa.—The Life History of the Liver Fluke.

THE ordinary meeting of this Society was held Nov. 14th, J. Marshall, Esq., F.R.S., President, in the chair. There was an unusually large attendance of Fellows and visitors. The evening was devoted to the interesting subject of parasitic diseases, especially the Bilharzia and Fasciola hepatica. A paper on the former subject, written by the late Dr. Lyle, of Durban, was communicated by Dr. J. Harley; and Drs. Cobbold and Crocker exhibited specimens of the parasite and allied forms. Mr. Thomas related his admirable research into the life history of the liver fluke. He deserves the credit of having conclusively determined the species of mollusc that acts as intermediary host of this parasite, so destructive to our flocks. He exhibited numerous specimens, and his relation of the developmental changes of the fluke was illustrated by diagrams. Other specimens of parasites were exhibited by Professor Ray Lankester, Dr. Bastian, and Dr. S. Mackenzie.

The following is an abstract of the paper on the Endemic Hæmaturia of the South-east Coast of Africa, by the late Dr. Vasy Lyle, of Durban. (Communicated by Dr. John Harley.) The author, in the first place, discusses the physical characters of the infested country, and the extent of the country infested. He states, as an almost completely proven fact, that the Bilharzia infests the whole eastern littoral of Africa, from Egypt to the Cape, and that the entozoon found amongst the people of the Nile valley is identical with that found in South Africa. It appears to inhabit the sluggish parts of rivers and low marshy lands, and to be absent from high lands; the interior plateau of South Africa being free from the disease. The present immunity of Port Elizabeth is attributed to the substitution of rain water stored in tanks for that of wells and pits. Opportunities were obtained of examining the bladder in a case of the disease, and both the male and female parasite. The bladder in one case was healthy near the neck, but crossed thence diagonally to the fundus by

fungous-looking growths, and the mucous membrane over these was granular and ulcerated, and contained embedded ova. One female Bilharzia was dissected out. The author agrees generally with the description given of the parasite, but differs in some minor points. In reference to the symptoms and progress of the disease, the author remarks that no symptoms of the affection have been observed antecedent to the appearance of the hæmaturia, the general course of the disease being that described by Dr. Harley in his communications to the Royal Medical and Chirurgical Society. Illustrative cases are given, and one of them contains the evidence of a Kaffir on the prevalence of the disease amongst the natives.—Dr. Cobbold had brought to the Society specimens of urine from five out of seven cases that had been lately under his care. One of these, which a year ago was loaded with blood, was now quite clear, but still contained ova, and the ciliated embryos hatched from them were shown under the microscope. He also exhibited specimens of the adult Bilharzia sent him by Professor Leuckart and Sir J. Fayrer, as well as specimens of the parasite from oxen and sheep, differing from the human varieties in the spindle shape of the ova. After referring to the discovery of the parasite by Bilharz in 1851, and his own discovery of it in a monkey in 1857, the speaker said that its clinical bearings and geographical distribution were dealt with by Dr. J. Harley in his paper read before the Society in 1864. The parasite had since been found in India as well as in Natal. Although from analogy it was thought to have its intermediate host in molluscs, the variety of mollusc had not been found—probably not a British form. He described the three modes of dealing with the disease as the “heroic,” the “do-nothing,” and the “rational” plans of treatment. Of the first Dr. Allen had lately given an example, advocating injection into the bladder of saturated alcoholic solution of santonin. This produced severe cystitis, and the fact quoted in support of its efficacy, that the patients did not return for further treatment, was capable of an opposite inference to that given by Dr. Allen. The second plan was based on the idea that patients will outgrow the affection. But Dr. Cobbold had under his care in 1870 a girl who was passing an enormous quantity of the ova, and is now strong and well. The treatment then adopted was tonic and nutritious, which succeeded, he believed, in saving her life. He therefore recommended treatment to support the system—quinine and iron, ample food, etc. Buchu was useful, and in bad cases it might be well to try such parasitocides as perchloride of mercury, given internally.—Dr. Crocker referred briefly to the case from which the embryos and ova of Bilharzia that he exhibited were taken. In that case the hæmaturia, which had been profuse, was now almost absent; but ova were still being found. The nature of the disease was detected by examining the clot microscopically.

Dr. J. Harley believed that the parasite gained ingress into the bladder through the urethra while bathing. It is not common in females, but almost every lad in infested districts suffers from it, and it was a practice with the natives to tie a tape round the penis to prevent its entrance. Although in Cairo the disease seemed to be taken by drinking water, in Natal, the view he held seemed more likely, especially as the parasite was located in the pelvic organs. He had early advocated treatment by injections into the bladder, and had used iodide of potassium and oil of male fern for this purpose. Dr. Harley referred to a case so treated with success. As to the apparent disappearance of the disease, mentioned by Dr. Vasy Lyle, Dr. Harley cited an instance of two young men from Port

Elizabeth, who were said to have had the disease in boyhood, and were supposed to be free from it when seen by him (Dr. Harley). But he found ova in the urine of each, and had later to attend them for attacks of renal colic and oxalic calculi. Dr. Harley concluded by referring to the author of the paper, who was a type of the honest scientific worker, and who seems to have been the only medical man in South Africa who had devoted such labor and patience to the investigation of this disease.

At the invitation of the President, Mr. A. P. Thomas, M.A. (of Oxford), then described his researches into the Life History of the Liver Fluke, researches which had been undertaken at the request of the late Professor Rolleston on behalf of the Royal Agricultural Society. After mentioning the ravages made by the liver fluke (as many as 3,000,000 sheep being lost by it in this country in the year 1879–80) and referring to the fact that hitherto the search after the particular mollusc supposed to harbor its larval form had been futile, Mr. Thomas described his plan of work. He thoroughly searched meadows for every species of mollusc likely to be an intermediary host, dissecting them without success, until at length he succeeded in finding in the small *Limnæus trunculatus*, a cylindrical worm or *Reedia* containing cercariae. The cercaria is of tadpole shape, and has the peculiar habit of encysting itself directly it is brought into contact with any solid object, the material for encystation being exuded from some lateral masses in the body of the larva. For some time the inquiry was arrested because of his inability to find any more specimens of the *Limnæus trunculatus*, even where they had abounded in the previous year. In last July, after floods, however, he found an ample supply in the flooded meadows. The snail in question is more truly amphibious than a water snail, is very small—about a quarter of an inch long—and wandering along the damp roots of grass, its presence may readily be overlooked. He now proceeded with infection experiments, and succeeded in proving that this mollusc was the sole intermediary host of the common fluke. At the same time he was enabled to study fully the metamorphosis of the latter. The liver fluke is very prolific, but so long as the ova remain in the liver they undergo no further change. In artificially hatching them, the embryo is seen to leave the egg by the sudden giving way of the operculum; and once in water the cilia with which the body of the embryo is covered came into action. The free swimming embryo has a spindle shape and is provided with a double eye spot (two masses of pigment), and is very sensitive to light. If the embryo comes in contact with a *Limnæus trunculatus* it begins to bore into its shell, the head papilla becomes elongated and sharp, and by a sudden movement the boring is effected, and the body of the embryo passes into the snail. As soon as it gets into the snail the body contracts, its outer layer is cast off, and it degenerates into a sporocyst. By proliferation of cells lining the body cavity and of cells in the body walls, masses of germinal cells are formed from which the cercaria is developed. The sporocyst usually develops in the pulmonary cavities of the snail and the parasite gets into the liver, feeding on the liver cells. The cercaria is formed by the rounded germ-masses becoming elongated, one end being pinched off to form a tail. When the cercaria has escaped and become encysted, it remains quiescent until swallowed by the sheep; when the cyst being dissolved the embryo fluke finds its way into the liver ducts of the sheep. Mr. Thomas concluded his statement by pointing out that the real preventive of the disease is salt, a small

quantity of which will not only kill the larvæ of the fluke, but the *Limnæus* also. The salt should be scattered over all land where the snail is believed to be present. It had also been found useful to feed sheep on salt, and this had been long a practice among farmers who had found it valuable in preventing sheep rot, but who had not thoroughly carried it out. Many other animals, including man, were liable to be infested by flukes, and in the case of man the parasite might be introduced through watercress.—Dr. Cobbold said that he exhibited specimens of flukes from the elephant, giraffe, etc., and that even whales, porpoises, and dolphins were liable to such parasites. He thanked Mr. Thomas for having conclusively proved the *Limnæus trunculatus* to be the intermediary host of the common fluke; and remarked that, curiously, a year ago he had believed that Leuckart had made the same discovery. But he had since heard that Leuckart thought it was another species of *Limnæus*, so that Mr. Thomas had succeeded in a search which the great German helminthologist had been so long pursuing.—Dr. J. Harley mentioned the case of a laborer who died from this disease, twenty-six flukes being found in the hepatic ducts, and the symptoms being most obscure. It was ascertained that his diet had consisted chiefly of bread and cheese, often accompanied by watercress.—Dr. MacLagan mentioned that a gentleman in Dorsetshire had told him that in 1879-80 he had lost none of his sheep from this disease, whilst all round there was great mortality. His immunity was attributable to his flocks being fed with salt.—The President thanked Mr. Thomas for his lucid exposition, and pointed out the great importance of the study of diseases of animals as throwing light on those of man, and of the importance of prevention in such diseases. It was a reproach that our troops should be exposed to such disorders, when the means of prevention were not far to seek.

Spontaneous Postures of the Hand considered as Indications of the Condition of the Brain.—Seventeen Cases of Epilepsy treated with Sodium Nitrite.

The ordinary meeting of this Society was held on Nov. 28th, J. Marshall, Esq., F.R.S., President, in the chair. In addition to the two papers read and discussed, several specimens illustrative of diseased conditions of the skull, the brain, and its membranes, collected from various hospital museums, were exhibited, as well as an excellent series of photographs from Professor Ziemssen's collection, showing the effect of isolated stimulation of the various facial muscles.

The first paper, entitled "Spontaneous Postures of the Hand considered as Indications of the Condition of the Brain" was communicated by Dr. Francis Warner. A posture is the relative position of the several members of the body with regard to one another, and the relative position of the individual parts of a member. Every posture is due to a balance of the muscles produced by some portion of the central nerve-mechanism. A weak child spontaneously holds out his hands in the "nervous posture." The limb is now free or disengaged; its posture is the spontaneous outcome of the action of the nerve centres. The wrist is slightly flexed, the metacarpophalangeal joints are extended backwards, the internodes being either flexed or straight. This posture is often seen in nervous children; it is usually bilateral. Explanation may be sought after Darwin's method—i.e., observe what advantage attends the posture. The following method appears preferable:—Analysis and analogy show a wrist drooped as in weakness, and the knuckle-joints extended as in conditions

of excitability. This posture is sometimes found in spastic contraction. The "energetic hand" may also be a permanent posture resulting from brain disease. The wrist is extended; the small joints are all flexed. This posture is the antithesis of the "nervous hand." The following axiom is assumed:—"If we see some spontaneous nerve-muscular action often repeated in the same and in different subjects, it may be assumed that there is some nerve mechanism corresponding which can act independently." In any particular case the existence of a special centre is strengthened if we can see its action when excited, and again when it is weak. In analyzing postures the following "principles" appear useful:—1. The contrast of small parts with large parts. 2. Inter-differentiation—i.e., the relative condition of the large and small joints. 3. Collateral differentiation—i.e., the relative condition of collateral joints. 4. Symmetry or asymmetry in a posture. 5. Excitation of weak centres. 6. General excitement or general weakness; in this case the stronger muscles produce the posture. 7. Antithesis—i.e., the principle that opposite postures may indicate antithetical states of the corresponding nerve-mechanism. 8. Anatomical analysis and description. 9. Analogy between postures. The following suggestions are offered as to determining whether a posture is the outcome of the spontaneous action of the nerve centres: The part must be free or disengaged. Look for analogous postures in brain disease. Look for analogous postures in infants, also in ancient art. Apply the "principles" above given to the case in question. Errors may be made by attributing all postures to the central nerve mechanism. Postures may be due to joint disease, local changes, and organic conditions—e.g., cardiac orthopnea, the effects of gravity, muscular rigidity, and local injury to nerve. Appendix: A table applying the principles of analysis to eight postures—viz., the nervous hand, the energetic hand, the hand in rest, the straight extended hand, the straight extended hand with thumb drooped, the convulsive hand, the hand in fright, the feeble hand. The paper was illustrated by a large collection of drawings and casts.—The President pointed out the difficulties that beset so apparently simple a subject, for so many factors were operative in these postures. The author deserved great credit for his painstaking inquiry and analysis of this complex matter.—Dr. Hughlings Jackson also spoke highly of the author's work, which he characterized as opening up a new subject in practical medicine. Dr. Warner had dealt with one of the most specialized parts, the hand, and it is the rule in all cerebral affections that the more specialized parts suffer in a greater degree than those whose functions are more general. As an instance of the latter, he mentioned the respiratory apparatus, where the same movements are being repeated continuously throughout life. But in the hand we have not only a part which can exhibit a vast variety of movements, but one which has a large number of small muscles carrying little weight; and the more intellectual the actions the slighter are the movements—e.g., the actions of the hand in writing, painting, and drawing, actions which might be contrasted with those of such a muscle as the deltoid, moving the whole limb to bear heavy weights. In a general sense in nervous disease the parts first affected are those of small muscles and small movement. In most cases of epilepsy the fit begins in such parts, so in chorea; so also in the commonest form of progressive muscular atrophy these muscles are the first to suffer. The tremor of paralysis agitans begins in the small muscles. Dr. Warner's work could be more generalized, to include attitudes in

disease, as that of paralysis agitans, which is the reverse of the attitude in cerebellar disease; or it may be applied to the face as in the loss of expression seen in double facial paralysis, which gives a sullen look to the patient; in paralysis agitans, where the face is fixed there is a puritanical or aged look. The paper was an inspiring one, and Dr. Jackson regretted that, having no special knowledge on the precise subject, he was unable to discuss it.—Dr. Warner explained that his object was rather to open up the subject of postures than to give many details, and he had therefore limited the remarks in his paper to two only of the natural postures of the hand. In the Appendix he had applied the same principles to the analysis of eight other postures without exhausting the list. For this study to be clinically useful it was necessary to take special types, from which many variations might arise; and he had taken as types such postures of the hand as had been recorded in works of art for centuries, and which were probably referable to particular conditions of the brain. Tronseau describes the hand in tetany, the fingers flexed over the thumb, and the arching of the metacarpus from its adduction. This arching of the metacarpus is an abnormal condition; another is the drooping of the thumb, which Dr. Warner believed to be the first departure from the normal in the weak hand. The face was even more specialized than the hand as regards its muscularity and movements, and the same principles of analysis might be applied to their study.

A paper was then read on Seventeen Cases of Epilepsy treated with Sodium Nitrite, by Dr. Charles Henry Ralfe. The author, in the first place, claims the credit of first introducing this drug for the treatment of epilepsy to Dr. Law, of Hastings, who was the first to administer it, and who has fully described the theoretical reasons which led him to employ it, together with an account of its physiological action in the *Practitioner* for June, 1882. Sodium nitrite in its action resembles nitrite of amyl and nitro-glycerine. It has one advantage over these remedies for the treatment of epilepsy; its effects are produced more slowly and are more permanent in character. The dose, the author's, should just fall short of producing full physiological effect. He advises that care should be taken to ascertain the purity of the drug, as many samples contain an admixture of sodium nitrate. The details of seventeen cases treated by the author in the out-patient department of the London Hospital is then given. Of these seventeen cases, three received no benefit, four improved slightly, one was a doubtful case, whilst nine benefited decidedly. Of all the cases, eight previous to treatment with sodium nitrite had been treated with bromide of potassium. Of these, three (Cases 1, 2, 3) had improved under its use, and went back when the medicine was changed to sodium nitrite. Of the other five, the bromide treatment was inefficacious from the first in three cases; and in two, though it had done good for some time, was losing its effect, and the patients were suffering from bromism. In four of these cases (9, 13, 14, 15) decided improvement followed the change to sodium nitrite, and the other (Case 7) improved to a lesser degree under its use. Nine of the patients commenced treatment directly with sodium nitrite. Of these, the disease in four was of long standing, and probably the patients had already been subjected to a course of bromide at other hospitals. Of these, two improved under sodium nitrite, and two received decided benefit. The remaining five cases were all tolerably recent ones. Of these, three received decided benefit, one slightly improved, and one was a doubtful case. Among the cases that received decided ben-

efit, the longest exemption from any kind of epileptiform seizure was in Case 17, who went eleven weeks without an attack, four weeks whilst under treatment, and seven weeks after leaving off the medicine. Case 14 went eight weeks without an attack, and had no relapse at the time he was last seen; he is still an out-patient and taking the medicine. Previous to commencing treatment he had on an average three fits a fortnight, and they were increasing. Case 16 remained free for a period of four weeks, and had had no recurrence when he gave up his out-patient letter. Case 9, who had a fit on an average every week, after taking the medicine was free for five weeks. The same result obtained with Case 15, who was free for one month. The author draws the following conclusions from these results:—1. That those cases in which bromide of potassium is of marked service are not generally suitable for a trial of sodium nitrite. 2. That those cases in which bromide of potassium does not agree well from the first will probably be found to improve under sodium nitrite. 3. That to patients who have taken bromide some time, and on whom the drug is apparently losing its effect, or who are suffering from bromism, sodium nitrite is useful as a change medicine. 4. That there is a class of cases, consisting chiefly of minor seizures or convulsive attacks, such as often occur in young persons, usually at night, in which sodium nitrite is especially beneficial.—The President, in inviting discussion, said that in epilepsy so many factors were at work, and the nature of epilepsy was so obscure, that it was difficult to explain the mode of action of drugs upon the disease; but the introduction of drugs was often based upon physiological grounds. Of course many cases of organic disease producing epilepsy were outside the category of remediable cases. He directed attention to a series of preparations collected from the museums of Guy's, University College, and St. George's Hospitals, illustrative of diseases of the cranium and brain producing epilepsy, and expressed the indebtedness of the Society to those gentlemen who had furnished the specimens for exhibition.—Dr. Law had but little to add to what he had written in the *Practitioner*. He had employed nitrite of sodium in a case upon the theoretical ground that cerebral anæmia was one of the factors in producing the fits; and had used the salt in preference to such compounds as nitrite of amyl and nitro-glycerine because of its great stability. Dr. Richardson in 1865 pointed out the similarity of physiological action of the nitrites of amyl, ethyl, etc., and was inclined to attribute their action to the nitrogen they contained.—Dr. Gowers, after reading Dr. Law's paper, had given nitrite of sodium to many patients—about twelve in all, and in only one did it appear to do any good. Some of them were patients who had taken bromide for some time without effect; others were cases treated by other drugs. In every case the fits continued, in one or two with temporary cessation which in one case lasted for six weeks, and then the fits returned in spite of an increase of the dose. And very often the fits cease for a time under any drug that has a considerable action on the system. Even if the theory of the action of the nitrite were correct, and its efficacy proved, he did not think that would establish the fact of cerebral anæmia in epilepsy, for flooding the brain with arterial blood would conceivably act beneficially on the nerve tissue without assuming a prior anæmia. Nitrite of amyl will check the spasm of tetanus. H. C. Wood, of Philadelphia, holds it to be more rapid in its action than chloroform in this disease, but no one has ventured to suggest the occurrence of anæmia of the spinal cord as the grounds for its use; the condition in

tetanus is rather one of hyperæmia. Dr. Gowers had also given nitro-glycerine in epilepsy both before and since Dr. Hammond's advocacy of it, but had not found it to have the slightest influence. The dose of nitrite of sodium he had given was ten grains increased to twenty; in one or two cases it had been continued for a period of five months.

Dr. Ramskill mentioned the case of a girl five years old who was treated with the nitrite, which was discontinued owing to the great increase in the number of the fits; bromide was then given with good effect. He had also had several similar cases; but he wished particularly to state his belief that the drug was not without dangerous effect, and referred to three cases in which alarming symptoms were produced by it. Dr. Ralfe's cases were probably chronic ones—e. g., cases of commencing sclerosis, where such treatment might do good; but he did not think it of value in idiopathic epilepsy. He agreed with Dr. Gowers as to any remedy having the effect of temporarily postponing fits, and also that rest alone or change in surroundings will do the same.—Dr. Coxwell gave brief details of three cases in which the nitrite of sodium treatment was compared with valerianate of zinc and bromide of potassium, and in each case fits recurred more frequently under the nitrite.—Dr. Hughlings Jackson considered Dr. Ralfe's facts too few, and the period of observation too brief, to draw favorable conclusions as to the efficacy of the remedy. He trusted he would pursue his investigations, as any new remedy which can be shown to be a little better than those at present used in epilepsy would be a gain. He would have liked more details as to the age of the patients, and the nature and duration of the attacks. For his own part, he laid great stress upon diet, and was especially careful in restricting nitrogenous food, a fact long ago insisted on by Heberden, and by other physicians, as Tronseau, James Jackson of the United States, Ireland, and West. So far as things go, bromide of potassium was the best; and although Dr. Ringer had demonstrated that potash salts were more depressant than soda salts, yet this was itself an advantage in epilepsy, where it was, above all things, desirable to bring the patient to a "low level." Tonics, as iron, and full diet, were bad. Adverting to the subject of "arresting" a fit, Dr. Jackson expressed his opinion that in the case of epileptiform seizures it was not a good practice to stop the fit—(e. g., by ligature) altogether at its outset, although it might be well to limit it to the limb. The effect of this is to leave the limb more paralyzed, but it prevents the fit becoming general, with the resulting loss of consciousness and general powerlessness.—Dr. D. Drewitt drew attention to the method, adopted with good results at the Children's Hospital, of the application of a silk seton in the nape of the neck.—Dr. Broadbent thought the cases too few and inconclusive to base any precise view of the action of the drug. He was not previously aware that the nitrite of sodium had analogous physiological action to nitro-glycerine; and would rather have thought that the nitrite would take up oxygen and be converted into a nitrate in the economy. He had met with two opposite conditions of the circulation in epilepsy—one of extremely low arterial tension and one of high tension—such vascular condition being probably a consequence and not the cause of the change in the nerve centres. Possibly the nitrite was of advantage in those cases where the arterial tension is low.—Dr. Wilks had not tried the remedy, but agreed with Drs. Gowers and Jackson that any number of remedies will arrest epilepsy, at least for a time. Very slight influences will produce a fit, and very slight influences will arrest it, so that

the results are not always to be attributed to the drug that may be given. He instanced a case where a toothache or gum boil arrested the fits, another where no fits occurred during an attack of erysipelas, and had several cases where epileptics had no fits whilst suffering from fevers. In one case of a young lady, who had most severe fits, an attack of small-pox cured her epilepsy without return. He was, therefore, very sceptical as to new remedies in epilepsy, and confirmed Dr. Ramskill's remark upon the influence of rest in hospital in temporarily averting fits. He had often employed setons, and he mentioned one case of a gentleman who had to give up a Government appointment on account of epilepsy, but who had since been free from attacks for eighteen months by wearing a seton.—Dr. Buzzard asked for information as to the dose, etc., of the bromide in those cases mentioned by the author where that drug had not been efficacious. The susceptibility to bromide varied with the individual; some cases of great severity were controlled by small doses; in other cases the drug had to be pushed to bromism before any effects were produced.—Dr. Ralfe, in reply, said that the paper was based on some rough clinical experiments which he had made on hearing from Dr. Law about his case. They were not all chronic cases, most of them being in children. He thought his results had been estimated too highly; for it must be remembered that in only nine out of the seventeen cases did the drug succeed in controlling the fits. To those who had been long taking bromide without benefit the bromide had been given in various doses. He thought a good deal depended upon the purity of the nitrite and the strength of the dose. He had found large doses to have no effect, and it was only after gradually trying smaller doses that he at length arrived at a dose of about twelve grains as the most suitable. Since the paper was written he had on one day prescribed the nitrite to three patients, two being cases of epilepsy, and one of asthma. All of these patients returned to the hospital suffering from the toxic effects with cyanotic symptoms. The sample of nitrite given to these patients was different from that previously described, and it had been set aside for analysis. It showed, however, that samples of the salt vary, and also that it was important to ascertain the physiological dose of each individual. He had also found marked differences as to their efficacy in epilepsy in two other samples, and suggested that possibly the negative results obtained by Drs. Gowers and Ramskill might depend on such differences.

The President directed attention to a series of photographs lent by Dr. Ziemssen, of Munich, showing the effect of stimulating the facial muscles separately, and interesting as an analysis of facial expression.

Resection of Portions of Intestine.

The ordinary meeting of this Society was held Dec. 12th, Professor Marshall, F.R.S., President, in the chair. The paper of the evening, by Mr. Treves, of the London Hospital, was a careful and clear exposition of the subject of resection of the intestine, and its reading was followed by a debate that was prolonged beyond the usual hour of adjournment. Several pathological preparations in illustration of the subject were exhibited from St. Thomas's Hospital and University College, and a large collection of the instruments employed in abdominal operations were also shown by Mr. Lund and Mr. Meredith.

The following is an abstract of the paper on *Resection of Portions of Intestine*, by Mr. Frederick Treves, F.R.C.S. Portions of gut have been

excised for various diseased conditions from all parts of the tube, from the pylorus to the rectum. Among the illustrative cases given of the various operations is Koberlé's, who excised two metres of the small intestine for multiple stricture with perfect success. In properly selected cases, resection would appear to be indicated in some forms of intussusception when all other means have failed, and when on opening the abdomen, the invagination is found to be irreducible; in gangrene of gut after strangulated herniæ, in gangrene after some forms of internal strangulation, in non-malignant strictures of the small and large intestine, and in malignant strictures that are yet local. Other things being equal, the mortality after resection would appear to depend more upon faults in the details of the operation than upon any other single cause. There are two procedures: in one an artificial anus is established after resection; in the other, the two ends of the divided gut are united by sutures, and the mass returned into the abdomen. The former method has been the more successful. There are many objections, however, to an artificial anus, especially of the small intestine, and there appears to be no reason why the latter method should not prove the less fatal if the technical defects of the procedure be remedied. The operation of uniting the bowel after resection presents these difficulties. It is not easy to maintain the two ends of the gut in accurate apposition while the sutures are being introduced. The sutures are apt to be irregular. The gut above the obstruction is usually much dilated, while that below is shrunken, and it has been found almost impossible to unite well these unequal parts. One of the most common causes of death, therefore, after the operation is due to escape of intestinal contents at the suture line. There is no reason, however, why the escape should not be as surely prevented as it is in cases of pyloric resection. "To meet some of the difficulties of the operation I have ventured to introduce the following appliance:—The gut above the part to be resected is secured by a special clamp lined with indiarubber, to avoid undue compression of the bowel. The gut below is secured in like manner, and the obstructed or gangrenous part is excised. The corresponding ends of the two clamps are then united by transverse bars, so that they form with the clamps a rigid square frame. By means of this frame the two divided ends can be very accurately approximated, and can be firmly retained in position while the sutures are being applied. As it is difficult to apply sutures to collapsed gut a sausage-shaped india-rubber bag about three inches long is used, that can be distended to four or five times its natural size through a small tube inserted in the centre of its long axis. This bag is sufficiently distended to make it firm, and one end is introduced into upper segment of the divided gut, while the other is introduced into the lower segment. The tube through which the bag is dilated thus occupies the suture line. After being introduced the bag is dilated to a good size. By this means a firm plug is introduced into the gut so as to form a substantial basis over which to apply the sutures. Moreover, by increasing the degree of distension of the bag, all inequalities in calibre between the two segments of the bowel can be overcome. Before the last sutures are applied the bag is emptied of air and is withdrawn, it being capable in its shrunken state of being drawn through a hole of the dimensions of a No. 12 catheter. If the sutures are properly applied—i.e., if the mucus membrane be not included in the stitch—there should be no danger of wounding the bag. At least fifteen or twenty sutures should be used. By means of this appli-

ance it is possible to excise portions of the colon through an incision in the middle line." In cases of stricture of the colon it is often impossible to diagnose the exact seat of the obstruction, and under such circumstances the abdomen has been several times opened in the middle line, and, the obstruction having been found, a second operation has been performed in one or other loin. Resection of the gut from the loin presents many difficulties, and can scarcely be performed without establishing an artificial anus. If colectomy were always performed through the middle line, it would, in cases of doubtful diagnosis at least, render one operation only necessary. The greatest fatality has been found in those cases of resection of the colon where the abdomen was first opened in the middle line, and the gut subsequently removed from the loin through another incision. The author lately resected some two inches of gut from the middle of the descending colon for epitheliomatous stricture through an incision in the middle line. The divided ends of the bowel were united by means of the appliance described, and the gut returned into the abdomen. The man had had symptoms of obstruction for some months, and was in *extremis* when the operation was performed. He died in twelve hours. At the post-mortem the gut at the suture line was found fully distended with fluid fecal matter, yet not the least trace of that matter had escaped from the intestine. The case serves to demonstrate that portions of the colon can be resected through the middle line, and that the gut may be so united as to prevent all escape of contents.

The President, in inviting discussion upon the paper, drew attention to a series of preparations on the table of various morbid conditions of the intestines from the museums of St. Thomas's Hospital and University College; and also to a large selection of instruments used in abdominal operations, exhibited by Mr. W. A. Meredith, of London, and Mr. Lund, of Manchester.—Mr. Bryant, in congratulating Mr. Treves upon his case and contribution to the subject, proposed, in the first place, to offer a little friendly criticism upon it. He regretted that Mr. Treves in dealing with the case had not performed lumbar colectomy, for the case was one of chronic obstruction, and clinically the probabilities were in favor of the disease being in the descending colon, so that if the lumbar incision had been made he would have come upon it and readily removed it. Of the two procedures, abdominal and lumbar, the latter was to be preferred as an exploratory operation, and even for colectomy, for at least six inches of the colon can be readily dealt with through the lumbar incision—i.e., if the bowel be not over-distended, as it was not in Mr. Treves' case. He praised the instrument invented by Mr. Treves as an admirable device; but it must not be forgotten that in cases of intussusception or internal hernia great lengths of bowel have to be dealt with, whilst the distended and inflamed condition of the bowel above the obstruction would be very difficult to unite with the distal collapsed segment. In cases of stricture, unless the diagnosis can be made very early—i.e., before there is obstruction—the same difficulty in uniting the two segments would be met with. In Mr. Treves case the cæcum (as is usually the case) was more distended than the colon immediately above the stricture, and this being so the clamp could be applied more readily. He also urged that in most cases of internal strangulation the inflamed condition of the gut would render it far more liable for stricture to ultimately follow upon its successful suture from contraction of the wound, just as stricture ensues in those cases of intussusception where the invaginated segment separates

by sloughing. It was for this reason that in his own case of colectomy he (Mr. Bryant) preferred making an artificial anus to attempting to suture the severed ends, of the bowel; although he admitted that Billroth's experience of pylorus resection showed that in cases of limited annular stricture such suture might be safe. Again, how would the mesentery be dealt with when a large piece of small intestine had to be excised? Although not prepared at present to adopt the measure, he trusted that his objections might be overcome and his opinion changed. Mr. Bryant added, that in the three cases (including Mr. Marshall's) where abdominal section had been first done and then lumbar colectomy, he had felt that a better result might have followed had the lumbar operation been chosen for exploration in the first instance.—Mr. Barker pointed out that wounds under aseptic conditions showed no tendency to contract, union taking place by first intention. That was true of wounds in the skin and serous membranes, and was quite as applicable to the intestine. Nor did he think many cases of intussusception when separation took place with recovery were followed by stricture; and he referred to one case where Dr. Peacock said that no symptom of obstruction followed, although the patient survived the intussusception many years. Nor does stricture occur after attacks of typhilitis and ileus. He did not think then Mr. Bryant's inference justified.—Mr. Howard Marsh alluded to the continued advances in abdominal surgery, and pointed out that in Mr. Treves' case interference came, as in so many cases, too late. The patient was so exhausted that colotomy even might have been fatal. He looked forward to the time when an early recognition of these cases would lead to very different results. But no surgeon hesitates to operate on strangulated hernia because it is too late to afford relief; and such a contingency must often occur. The case of cancerous stricture of the colon in which he (Mr. Marsh) had performed abdominal section, was that of a woman, aged forty, who was suddenly taken with intestinal obstruction when at work. An accurate diagnosis was impossible, and looking to the age of the patient alone colotomy might have been preferred. The case proved to be annular stricture of the sigmoid, and he made an artificial anus in the gut above it. Mr. Marsh then narrated cases which had recently come before him, to show how little reliance could be placed on the numerical method for diagnosing the site of a stricture in a subject beyond middle age. (1) A man, aged fifty, suddenly seized with symptoms of obstruction whilst walking in the street. Colotomy performed without relief. Post-mortem: abscess in connection with appendix vermiformis, which had burst into the peritoneal cavity. (2) Obstruction in an elderly lunatic, presumed to be in sigmoid; no operation. Post-mortem: two gall-stones impacted at ileo-cæcal valve. (3) Case with history of increasing constipation; from age of patient stricture thought to be in colon, but as its precise seat was uncertain right colotomy was done. There proved to be ulceration of the lower six inches of the ileum. Such cases showed that the numerical method might be carried too far in diagnosing the seat of a stricture in the large bowel; and, further, they demonstrated the advantage of the median incision over a colotomy which is done without certain knowledge of the position of disease. The difficulties raised by Mr. Bryant might not prove to be well grounded, and he thought that eventually the abdominal operation would come to be preferred.—Mr. Harrison Cripps said that although Mr. Treves had demonstrated its possibility, he would have to show a fair pro-

bability of success in the operation before it could be generally adopted; and in the case he related death occurred before the separation of the sutures, or inflammatory softening might have led to faecal extravasation. He himself had practiced excision of the rectum in cases of cylindrical epithelioma, in which disease it is right not only to relieve the obstruction but to remove the diseased mass, which can be done without fear of recurrence. He would prefer making an artificial anus after resection of the bowel to the attempt at suturing the divided ends on account of the risk of the latter, with the possibility of subsequent stricture. Stricture follows removal of the lower end of the bowel, and can only be obviated by the continued use of bougies—a measure, of course, inapplicable to the intestine within the abdomen. In Mr. Marsh's case an artificial anus was made, but it would have been better still had the diseased part been excised.—Mr. Macnamara observed that abdominal surgery was undergoing a great change, and now that we know abdominal section can be done without much risk, operations on the intestines will be more frequent. Sutures of wounded intestine did well; he had three cases in which recovery took place, and no stricture followed; this being so, he thought Mr. Treves was right in saying that success mainly depended on the manner in which the details of the operation were done; faecal extravasation need not be feared if care be taken. Nor did he agree with Mr. Bryant as to the frequency of secondary strictures; for if so, how could the immunity from stricture after dysentery, where large sloughs separate, be explained? Apart from this, be believed with Mr. Barker that the operation of suture could be done with very little risk of subsequent inflammation. After hearing the paper and seeing Mr. Treves' instrument, he should be inclined to adopt his suggestion.

The President said that as regards this operation of resection of the bowel, they were on the verge of improvements, and that Mr. Treves' contribution was valuable as an effort to advance the subject. He thought with Mr. Bryant that there would be considerable difficulty sometimes in getting the dilated bowel into apposition with the collapsed portion, a difficulty which he feared would not be wholly met by Mr. Treves' instrument, for he could not see how the dilated gut could be made to contract. It was just possible in future that electricity might be called in to cause such contraction of the upper segment and dilatation of the lower, so as to approximate the calibre of the two portions. In his own cases he was perfectly sure that no instrument could have made them equal. Mr. Treves' clamp was a great improvement on Martigny's, which did not bring the divided ends together. He agreed with Mr. Treves as to the use of a large number of stitches, and suggested that the puckering following the union of the two unequal-sized ends of bowel might be met by putting the sutures in each end at unequal distances apart. Although the formation of an artificial anus was simpler and safer, they must not be content with that, but seek a better method, nor be deterred by some failures; and there was sufficient to encourage these endeavors. He agreed with Mr. Barker as to the slight fear of stricture following on suture, especially as contraction is due to granulations. He was still of opinion that in a case of chronic obstruction (and Mr. Marsh's cases were acute ones) the lumbar operation was preferable; but this was only his view, and he might come to prefer the median incision. In his own cases he failed to withdraw the diseased bowel through the median incision; it was at the lower part of the colon, and he did not think of dividing the peritoneum.—Mr. Treves, in reply, said that

the case he had related was an obscure one, there being no symptoms pointing to obstruction of the descending colon; and it was under the impression that the disease was in the ileum that he opened the abdomen. Had he felt sure of its actual seat he would have done the lumbar operation. In reply to Mr. Bryant's objections, he referred to Koeberlé's case, where two metres of intestine were successfully removed, the mesentery requiring only twenty-four ligatures. The dilating bag, which he had used in his own case, considerably aided in distending the collapsed bowel to the size of the distended part. Again, the most successful cases of resection had been cases of gangrene after strangulated hernia, for which Kocher had six successes out of eight operations. Subsequent stricture was very rare in intussusception. Leichtenstein, who collected upwards of 900 cases, says that fatal stricture followed in only 3 to 4 per cent. of the cases of spontaneous separation of the invaginated bowels. He agreed with Mr. Marsh's remarks about too great reliance being placed on statistics; and it must be remembered that in many cases of chronic obstruction the onset of symptoms is often acute. The risk of extravasation could not be so great in the case of the intestine as in that of the pylorus, when it had been quite prevented. In cases of great disparity in calibre between the two portions it would be well to make an oblique section of the lesser segment, as in the pylorus operations. Lastly, in strictures of the small intestine no treatment was available except that afforded by resection.

CLINICAL SOCIETY OF LONDON.

Hysterectomy.—Spina Bifida.—Diastasis of Clavicle.— Local Treatment of Diphtheria.

THE ordinary meeting of this Society was held on Friday, Nov. 10th, Mr. J. Lister, President, in the chair. For the first time, in accordance with the new regulations, card specimens were shown. The President announced that he had heard from Prof. Pantaleone, of Rome, expressing his gratification at the honorary membership of the Society recently conferred upon him. Mr. Clutton's cases of spina bifida excited a good deal of discussion, at the close of which the President nominated Messrs. Clutton, Pearce Gould, Howard Marsh, and Parker as a committee to inquire into and report to the Society upon the results of Dr. Morton's treatment of this deformity.

Mr. Golding Bird narrated a case of Removal of a Fibroid Tumour, with Extirpation of the Uterus, that had ended fatally. The patient was thirty-seven years of age, and had had the tumour for three years. Its increasing size, the pain and weight accompanying it, and the repeated and prolonged attacks of nausea occasioned by it, compelled her to seek surgical relief. The tumour—the size of the uterus at six months—grew from the anterior wall of the cervix, and lay between this and the bladder, with the latter of which it was intimately connected. The uterus itself was all but drawn out of the pelvis, and the two ovaries, both cystic, could be felt through the abdominal parietes, and prior to the operation were thought to be bosses on the tumour. The operation was fully described, and special mention was made of the use of an apron of green carbolized protective well tucked in over the intestines when the abdomen was opened, whereby they were easily kept out of the way and sheltered from the spray. The tumour had its peritoneal investment circumferentially divided where it was reflected

on to the pelvic walls or viscera, and it was then shelled out from its bed, the broad ligaments being previously divided. The union with the uterus was intimate, and had to be severed, while the connection of the fibres of the tumour with those of the bladder rendered the operation very difficult. All bleeding was stopped with carbolized silk ligatures, and the peritoneum, where divided between the rectum and bladder, was united with a continuous suture at the completion of the operation. The uterus and ovaries were removed after the tumour, a pedicle being formed out of the cervix uteri; it was tied in four parts, as in Erichsen's method of tying *nævi*. Before the closure of the peritoneum a rent in the bladder had to be carefully sewn up; a catheter was tied in. The general conduct of the case was like that of ovariectomy. For forty eight hours all went well, and then severe vomiting set in, which eventually exhausted the patient, and caused her death on the fourth day. The post-mortem showed repair to have been perfect as far as it had gone; there was no evidence of the urine having passed beyond the limits of the bladder. There was no suppuration, and only slight pelvic peritonitis. There did not seem to be enough to account for the vomiting, and the author explained this symptom as depending upon some idiosyncrasy of the patient, inasmuch as when she had typhoid fever ten years before, vomiting severe enough to threaten life was then the most prominent symptom. The specimens removed at the operation and the parts reserved at the post-mortem were exhibited.—Mr. Knowsley Thornton would like to ask Mr. Golding Bird as to two points in the case which his record seemed to omit: What was the pulse rate? He did not attach much importance to temperature alone in these cases, but had frequently seen patients die of incessant vomiting without any marked high temperature, but with a constantly ascending pulse. He believed such deaths were from septic absorption. In this case everything was specially favorable for such a result, in spite of the use of Listerian details, because the uterine stump, which always contains causes of putrefaction, was ligatured and then enclosed with a mass of other wounded and ligatured tissues in a space between the closed peritoneal flaps and the tissues forming the floor of the pelvis, with no possible outlet for effused materials except through the cervical canal, which was closed by the constricting ligatures. Supposing the fluids in this space putrefied, as was most likely to be the case, their only outlet was through the sutured flaps into the peritoneum, and, doubtless, this was the origin of the eight ounces of red serum found there after death. The wounded bladder, with catheter tied in, would also be a very likely centre for sepsis spreading into the peritoneum. The absence of anything to account for death, when the post-mortem is made, is a special feature in these cases of septicæmia. The very peritoneal absorption which causes death itself removes the evidences. The second point he would ask for information upon was, What was the sufficient reason for such a serious operation? Mr. Bird had stated that the patient was in fair health, and that menstruation was not excessive. The fibroid was evidently quite a small one. What was the justification for this fearful operation? The authorities had long laid it down as a rule that hysterectomy for fibroids was only justifiable when life was in danger, either from hæmorrhage, excessive growth of the tumour, or some other cause. The mere wish of the patient ought not to be considered in these cases. He had himself on some previous occasions expressed sanguine views as to the future of hysterectomy, but recent observations and

experience had led him to modify these views somewhat, especially as it was becoming the fashion to remove the uterus for fibroid disease in cases in which there were no urgent symptoms. The results of the operation recently in this country by the wire *serre-nœud*, and in Germany by the elastic ligature, were very encouraging, but the operation was still a very dangerous and formidable one, and ought only to be undertaken in grave cases. From what Mr. Bird had said as to the condition and position of the ovaries in this case, it seemed to have been a specially suitable one for removal of the uterine appendages, and this has been proved to be a much safer and a more successful process. Mr. Lawson Tait had pointed out a fact which he himself could corroborate—viz., that the ovaries are very commonly cystic along with fibroids of the uterus. Mr. Tait thought that the cystic ovaries cause the fibroids, but they are too often absent for this to be true. Mr. Thornton was long very sceptical as to the cure of fibroids by the removal of the uterine appendages, but he had now convinced himself that Mr. Tait was right in this matter. He had tried the operation in a small number of carefully selected cases, and had met with uniform success; all the patients had recovered; and all in the course of from five months to a year had lost their fibroids by gradual absorption. He did not attribute the result to the mere removal of the ovaries, but chiefly to the great alteration in the blood-supply, when all the enlarged vessels about the ovaries and tubes were tied. He had tested the operation in cases of subperitoneal fibroids, mural fibroids, and fibro-cystic disease, and in all the result had been equally good. With the statistics of this operation as to mortality, he did not think hysterectomy was justifiable without a previous trial of the safer operation of removal of the uterine appendages. At the same time it must be remembered that this operation was often a very difficult and dangerous one, and might end in the necessity for the performance of the still more dangerous hysterectomy from uncontrollable hæmorrhage. This accident happened to himself in two of his early cases. In reply to a question from the President, Mr. Thornton said that his cases of removal of the uterine appendages had not only all recovered, but had in course of time their uteri restored to their normal condition.—Mr. Golding Bird replied that Mr. Bryant had advised him to proceed at once to removal of the entire organ rather than attempt incision of the uterine appendages at first. He had relied more upon the temperature than the pulse, especially as the patient was liable to great rapidity of the pulse from emotional causes.

Mr. Clutton related a case of Spina Bifida cured by Injection of Iodine. When three weeks old a child was brought to St. Thomas's Hospital, and was found to be a well-nourished, healthy child, with the exception of the above imperfection. The spina bifida was situated in the lumbar region, small, and with exceedingly thin walls. The impulse when the child cried was very marked, and the aperture in the lower canal large. There was no paralysis of the lower limbs, and the cyst, examined by transmitted light, did not appear to contain the *canda equina*. The skin had been so stretched that the walls were quite translucent, and would evidently have soon given way and allowed the fluid to escape. A week after it was first seen, and when the child was four weeks old, the cyst was injected with a drachm and a half of Morton's fluid, as little as possible of the contents of the sac being allowed to escape; a pad with collodion and bandage completed the treatment. The mother was instructed to keep the baby on

its back, and prevent, as far as possible, the gravitation of the fluid into the vertebral canal. The constitutional disturbance was very slight, and on the third day the child was in its usual health. The cyst began immediately to shrink, and by the end of a week the skin was in loose folds. At the end of the third week there was nothing to be felt of the spina bifida, except a small puckered lump of cutaneous tissue. Mr. Clutton also mentioned a case of Occipital Meningocele, which he had treated by injection of iodo-glycerine without any effects, good or bad. And also another case of Lumbar Spina Bifida, with a very thin sac, in which the injection of about a drachm of the iodo-glycerine solution was immediately followed by the sudden death of the child.—Mr. Morratt Baker asked whether in the last case any fluid was withdrawn previous to the injection, and also what position the child was placed in. The record of such cases was very valuable as a guide to practice.—Mr. Pearce Gould asked Mr. Clutton whether in his first case the sac was covered with skin, and whether the fluid withdrawn contained sugar. The most favorable cases for injection were those in which the deformity consisted only of a hernia of the dura mater, the fluid being arachnoid fluid. As an instance of the fact that spontaneous cure occasionally occurred in the worst cases, he described a case of a very emaciated infant who was recently under his care with a large lumbar spina bifida which had burst, and a great part of the sac had sloughed; yet the tumour underwent a spontaneous cure, although the child died of marasmus.—Mr. A. E. Barker had operated upon a case very much like the last one referred to by Mr. Clutton. The child was kept upon his back for some time after the injection. The operation had not the slightest effect upon the tumour, and he heard later on that the tumour burst and the child had died.—Mr. Howard Marsh mentioned the case of a child four months old. The tumour was not large, covered by fairly healthy skin, but was increasing. He injected the tumour with about one drachm of the iodine solution; the child became completely collapsed and died immediately after the operation. At the Children's Hospital the results on the whole have not been successful.—Mr. C. Heath said that the injection of iodine into the cavities of the brain and spinal cord was not necessarily fatal. He had had under his care a case of anterior meningocele in a child six years old which had been previously injected with iodine by Sir James Paget without injurious effects. He thought that talipes calcaneus was very common in these cases.—Mr. R. Parker had injected about twelve cases without meeting with any fatal result like Mr. Clutton, or other visible effect of the injection, but he had had only one successful case. The result depended upon the size of the spinal aperture, and whether the spinal cord were involved or not. In his successful case the sac was covered with healthy skin, and he injected less than half a drachm of the fluid every week for some weeks. He thought talipes calcaneus was not always present, in some cases it was unilateral or equino-varus.—Mr. Godlee added a case to the list of successful cases. The tumour was small, with a thin wall, and was cured by a single injection.—Mr. Bennett had had only one case of this kind, and there the injection was unsuccessful. The sudden death after the injection of the tumour might be a mere coincidence in some cases, as was shown by a recent experience of his own. Not long ago he planned to inject a spina bifida on a certain day, but owing to the child being then unwell he postponed it, and the child died from convulsions while going home in the omnibus.—Mr. Morratt Baker mentioned a case in which the

tumour was cured, but hydrocephalus increased, and gradual loss of power in the lower limbs came on.—Mr. Clutton said that in all his cases the child was kept lying on the back, and he injected slowly; he only withdrew a small quantity of fluid, and that gave a distinct reaction of sugar. In both cases there were patches where there was no skin at all, and the sac was like tissue paper. In the first case there was no raw surface, in the latter the sac was partly ulcerated. The aperture of the sac into the theca vertebralis does not correspond with the size of the aperture in the bones.

Mr. Christopher Heath related a case of Separation of the Epiphysis of the Clavicle by Muscular Action. A boy aged fourteen, whilst raising his arm violently to bowl at cricket felt something give way at his collar-bone. The inner end of the clavicle was found to be unduly prominent, and presented a sharp edge beneath the skin, quite unlike the smooth end of a bone, covered with articular cartilage. The supra-sternal notch was quite distinct and equally defined on both sides, and a thin lamella could be felt on the right side, intervening between it and the gap caused by the starting forward of the inner end of the clavicle. The treatment consisted in laying the patient down, when the bone at once slipped into its place, and it was retained by a plaster-of-Paris bandage. Mr. Heath referred to the great rarity of the accident, and the diagnosis of it from dislocation of the clavicle, and insisted upon the great utility of the plaster-of-Paris bandage in fractures of the clavicle and humerus.—Mr. Lister said this case was exceedingly interesting and rare, if not unique. The diagnosis was no doubt correct, both from the sharpness of the projecting fragment and the presence of the lamella in the site of the injury.

Dr. Goodhart read a paper on six cases of Diphtheria treated by the local application of Borax or Boracic Acid. In four a saturated solution of boracic acid in glycerine was used, the application being made in part by a hand spray, in part by the laryngeal brush, and as often as every two hours in some cases. In the other two a diluted solution of the glycerine and boracic acid was used. The first case was a very severe one, and it died from renal complications on the seventh day; but the boracic acid and glycerine seemed to be so successful in relieving the throat symptoms, and in preventing the re-formation of the membrane, that it was determined to try it again. Of the other five three had croup as well as membrane on the fauces; one had nasal diphtheria; all had albuminuria. All recovered. Tracheotomy was necessary in one case, and the glycerine and boracic acid were freely applied to the interior of the trachea and larynx from the wound, and to the surface of the wound itself, and it seemed to be very beneficial in loosening, dissolving, and preventing the re-formation of membrane. In another case it is believed that tracheotomy would have been necessary had not the vigorous application led to the expulsion of membrane by the mouth. In all cases it seemed to give such relief that very little difficulty was experienced in carrying out the treatment. Both borax and boracic acid have been occasionally in use as a topical application in diphtheria, doubtless, for a long time past, but not, so far as is known, with any decided success; nor can it be supposed that any remedy will not often show a good proportion of failures in combating a disease such as this. It is enough to say that these agents are known to be good antiseptics, that their action is harmless when not beneficial, and that they are certainly useful in some cases.—Dr. Phillips had carried out the treatment in the first of Dr. Goodhart's cases. He

referred to two other cases similarly treated, in each of which tracheotomy was performed in a few hours, and every attempt to remove the membrane was made, but the children died, and in each case the membrane was found extending down into the smaller tubes. The strength of the solution is one part of glycerine to three of borax diluted with an equal part of water when used as a spray.—Dr. O'Connor had notes of nearly forty cases of diphtheria, but he had not met with much success in the use of a watery solution of boracic acid. He thought the best application on adults is a solution of chlorate of potash. He had often found that the membrane reappeared on its original site, thinner but evidently of the same nature as at first.—Dr. Longhurst thought the treatment was good because it was non-irritating; much good was not to be looked for from local treatment of a disease which is essentially constitutional.—Mr. Lister remarked that each physician extolled his own application for diphtheria. He had received striking reports of series of cases without any fatal issue treated locally by tincture of iodine. But its infective character clearly showed it was a local disease. Boracic acid is a wonderfully efficacious antiseptic, as is seen when it is applied to putrid onychia, for example. It may very well act in this way on the membrane in diphtheria. Boracic acid, by the aid of heat, may be mixed in any proportions with glycerine.—Dr. Goodhart said that the constitutional nature of the disease was no argument against local treatment, as the disease is so often fatal from its local effects.

The following card specimens were shown:—1. A Case of Transpatellar Excision of the Knee, by Mr. Golding Bird. 2. A man from whom the Tongue and part of the Lower Jaw were removed in 1876 for Epithelioma, no recurrence, by Mr. C. Heath. 3. A Case of Spontaneous Partial Dislocation of the Clavicle, in association with Lateral Curvature of the Spine from an unreduced Dislocation of the Hip, by Dr. Clippingdale. 4. A successful Case of MacEwen's Operation for Genu Valgum, by Mr. Keetley.

Symmetrical Congestive Mottling of the Skin.—Lumbar Nephrectomy for Carcinoma.—Subcutaneous Rheumatismal Nodes.

The ordinary meeting of this Society was held on Nov. 24th, J. Lister, Esq., F.R.S., President, in the chair. The proceedings were interesting, especial attention being given to the subject of renal surgery, arising out of a case communicated by Mr. J. Adams; subcutaneous rheumatic nodes were well shown in two cases contributed by Dr. Duckworth, who read a paper on them; whilst Dr. Cavafy detailed the particulars of a peculiar cutaneous mottling, of which he showed two examples. Mr. Howard Marsh exhibited a child with very extreme deformity of the skeleton from rickets.

Dr. Cavafy read a paper on Symmetrical Congestive Mottling of the Skin. In this paper two cases of a curious affection of the bloodvessels of the skin are described. The first was a young woman, aged twenty-two, shown to the Society, who was first seen in March, 1882, when the condition had existed for three years. It began as a reddish mottling of the left shoulder, which gradually spread down the arm, and soon afterwards appeared on the right arm, the cheeks, and both thighs, gradually increasing in intensity. At the date of her first visit the skin of both cheeks was mottled with blotches and irregular rings and streaks of a bluish-red color, most marked on the right side, not prominent, and covered by normal epidermis. Singular, dull, bluish red maculæ and

irregularly confluent blotches and streaks forming reticulated annular and gyrate figures occupied the exterior surfaces of both arms and forearms and the backs of the hands, being especially distinct over the left wrist. The front and outer surface of both thighs near the knees was similarly mottled, but in a much less degree. The blotches and streaks were not sharply circumscribed, and disappeared completely on pressure, leaving in some spots a delicate fawn-colored pigmentation. The marking also disappeared from the arms when they were held up, and returned when they were allowed to hang down. The neighboring skin was normal in all respects and the general health perfectly good. The girl had rheumatic fever a year before the mottling commenced, but the heart was unaffected. The only departure from perfect health was a liability to "dead fingers" and occasional dyspepsia. She continued to attend for a month, with no change in the state of the skin. The markings were always intensified by cold; they never completely disappeared, and were throughout unaccompanied by pain, numbness, tingling, or any abnormal sensation. She is still in the same condition. The second patient, also shown to the Society, is a healthy young woman, aged twenty-one, who has been under observation since August, and in whom the affection has existed eighteen months. It began over the ankles, and gradually spread to the legs and thighs. Twelve months later the arms became affected, and quite recently blotching has begun on the waist; the face has remained free. The mottling is an almost exact counterpart of that in the first case; but more extensive and of a deeper bluish-red color over both legs and the front of the thighs, especially near the knees. It is situated on the exterior surfaces chiefly, but also extends slightly over the flexor sides. The condition above described was only due to venous stasis or passive congestion of the skin, and appears to be an exaggeration of the marbling often seen on the skins of children and young persons after exposure to cold; but in the above cases, although cold intensifies the marbling, the congestion remains more or less evident at all times. It is probably due to a vaso-motor neurosis, but the share taken in its production by arteries and veins is not easy to apportion. The affection appears to be quite harmless, and has not led to any changes except pigmentation, and that only slightly; but the disfigurement, especially when the face is attacked, is considerable. The treatment employed has not influenced the condition in any way.—Dr. S. Mackenzie said the cases were interesting and rare, such a condition seldom being so marked and permanent; and Dr. Cavafy's explanation of it was probably correct. The cases had a superficial resemblance to similar conditions due to direct exposure to heat, as from much standing before a fire. A condition of vaso-motor neurosis of the extremities has been described by Weir Mitchell, of which Dr. Mackenzie has seen one case; but this differs materially from these present cases.—Dr. Glover asked if the effect of a bandage had been tried. He was much struck by the good effect of such a measure in a case of long-standing purpura of the legs, where the application of an elastic stocking resulted in a cure. The President alluded to the symmetrical character of the mottling proving to be due to a neurotic origin.—Dr. Cavafy, in reply, said that the pigmentation, due to exposure to a fire, was excluded by the fact that the color could be pressed out of the part, and that neither patient had been so exposed; further, the mottling in the present cases is diminished by heat. The vaso-motor neurosis of Weir Mitchell, of which a case was brought before this Society by

Dr. A. Sturge, is different. The closest alliance was, perhaps, to local asphyxia, which may lead to symmetrical gangrene (Reynaud). The present cases might be a minor degree of that condition. Dr. Glover's suggestion was only applicable to the extremities.

Mr. Jas. B. Adams read notes of a case of Lumbar Nephrectomy for Carcinoma. The patient, a male, aged thirty-nine, had intermittent hæmaturia for two years; pain in right loin; latterly profuse hæmorrhage from the kidney, leading to marked anæmia; blood, pus, triple phosphates, and epithelium in urine. The disease was clearly located in the right kidney, but its exact nature was not certain. The operation was undertaken in order to explore, and, if necessary, to remove the right kidney. By an incision parallel with the lower border of the last rib, the kidney was easily explored and found to be the seat of a new growth, which had increased its size to about double the normal. In order to extract the organ it was necessary to enlarge the incision upwards; the organ was adherent to the peritoneum, and in separating it the serous cavity was opened. Owing to the size of the tumour, the ureter and vessels could not be tied separately, but were encircled *en masse* by a whipcord ligature. The peritoneal wound was closed with a catgut suture; the skin wound was freely drained. The hæmaturia ceased at once. The wound healed in a few weeks; but the patient gained no strength, suffered much throughout from cough, and was transferred back to the care of the physician, and died forty-four days after the operation, with effusion into both pleuræ, plugging of the left renal vein, and numerous secondary deposits in the lumbar glands and on the ribs.—Mr. Clement Lucas congratulated Mr. Adams on the success of the nephrectomy; though unfortunately the disease was too advanced for complete eradication. He had twice explored the kidney this year. In one case there were typical symptoms of stone; although the man had a severe rigor before passing the blood, which was attributed to his being moved. Mr. Lucas cut down on the kidney and punctured it in as many as five or six places for the depth of an inch and a half; no bleeding occurred, but the kidney appeared to be puckered. It was probably a strumous kidney. He mentioned these cases in order to encourage physicians to explore the kidney more readily in doubtful cases. No disturbance arose from the exploration, and the wounds healed rapidly and painlessly. The operation, then, might be regarded as perfectly safe, with no more danger than an incision of similar length in the calf of the leg.—Mr. Golding Bird asked Mr. Adams whether the opening was enlarged in a vertical or horizontal direction.—Dr. Fowler had lately had a case under his care with symptoms of renal calculus in which Mr. Morris explored the kidney, punctured it in several places, without finding a stone, and the wound healed perfectly.—Dr. Douglas Powell asked for the results of cases where the operation is completed and the stone removed, but his impression was that many cases were disastrous in their results. He thought that we should not consider too much the fact that the kidney had been explored without finding a stone without ill results. These cases of stone in the kidney often go on for many years, and eventually the stone is discharged from the bladder. Therefore he did not think nephrotomy an operation of necessity or always justifiable. It would be a matter of importance as a guide to its performance if a diagnosis could be made as to the size of a stone. A small stone will give rise to as severe symptoms as a large one; and he cited a case where a small stone was eventually passed, but the patient returning later with renal

symptoms, an exploratory incision was made, and no stone was to be found.—Mr. Barker said that for the very reason urged by Dr. Powell the kidney ought to be explored. A stronger reason still for calling in the aid of the surgeon is that these operations can be done without any risk. He alluded to a case in which all the symptoms of stone occurred in a child; he explored and punctured the kidney without finding a stone. The wound healed rapidly. If all the cases of exploration were recorded it would encourage the routine resort to the procedure. The point between nephrotomy and nephrectomy turns upon the extent of disorganization of the renal tissue. A small stone may be removed from the kidney without any risk whatever; but the case is altered when much disorganization of the kidney is present.—Dr. Wilberforce Smith alluded to one point in the diagnosis of stone in the kidney—viz., that of treatment by copious water-drinking, so as to produce diuresis. It was his habit to tell the patient to keep his urine down to a low specific gravity. There is prompt and considerable relief; the hæmaturia ceases and the pain is modified.—Mr. Haward, recurring to Mr. Adam's paper, asked as to the diagnosis between stone and malignant disease. There was considerable enlargement of the kidney; but was the examination made under an anæsthetic? In that way a stone may be felt in the kidney. Mr. Haward had succeeded in palpating an enlarged kidney by this manner in a case related last year. He also asked whether Mr. Adams had noticed great frequency of micturition, for a stone in the kidney is often accompanied by an irritable bladder, as Sir B. Brodie long ago pointed out.—Mr. H. Marsh, in reference to the question of making out a large kidney under an anæsthetic, said that in a case he related last year, no one succeeded in palpating the organ; but when he came to operate it was found to be very large indeed.—Mr. Adams, in reply, said that he enlarged the opening in a vertical direction, almost at right angles to the first incision. If he were sure that the kidney was very large and occupied by a large growth, the abdominal section would be preferred. He did not think that Dr. Powell's application of the term "disastrous" to exploration of the kidney was justifiable; and the operation is not performed except the patient is in much suffering and unable to perform his duties. He was in favor even of leaving a stone in the bladder if there was no suffering. The decision to remove a kidney would be based on the condition of the organ. This patient was examined thoroughly under an anæsthetic; but the difficulty or ease of the diagnosis will depend greatly on the amount of subcutaneous fat in the individual.

Dr. Dyce Duckworth read notes of two cases of Subcutaneous Rheumatismal Nodes. Case 1. S. C—, aged twenty-four, domestic servant, came to St. Bartholomew's Hospital on account of painful swelling on the right hand and knee. She had had no serious illness, no rheumatic fever or chorea. Suffered for eight years past with pains in the joints and limbs. Crackling in the larger joints was noticed. The nodules began eight months previously on the right hand, elbow, and knee, and are found to be quite subcutaneous, painful on pressure, and attached for the most part to sheaths of the tendons or deep fasciæ. The fingers were knotty at the joints and the right little finger was turned outwards at the last phalanx (not as the result of injury). The first sound of the heart was found roughened and somewhat reduplicated. The urine was alleged to be occasionally thick. The patient was exhibited, and casts of the right hand and knee were also shown.

In three months time it was found that some of the nodules had grown larger and that new ones had appeared. Signs of slight hypertrophy of the left ventricle of the heart were noted, and the first sound was rough and reduplicated at the apex. Treatment by cod liver oil and iodide of iron and potassium had not proved of material service, and there were still articular pains. The nodules ached more in damp weather. Case 2. E. L—, aged nine years, a school girl, had suffered from pains in the feet, knees, and arms for two months, and at that time nodules were first seen on the ankles, elbows, and knees. The legs and hands were also swollen "as if dropsical." There was no history of chorea. Nodules of various sizes were found on the sheath of an extensive tendon on the metacarpus, on the olecranon, on the spine of a dorsal vertebra, on both patellæ, and on an external malleolus. The nose and finger-ends were clubbed. The cardiac physical signs indicated mitral regurgitation. In three weeks the nodules on the patellæ appeared larger. The child ceased attendance, and its parents could not be traced subsequently. A cast of one knee was taken at the first visit. Both cases were well-marked examples of rheumatismal subcutaneous nodules. Both occurred in females, as is found to be the case in most instances. The nodules have persisted longer in the first case than has hitherto been previously noticed—fourteen months against five—and the age of this patient is more advanced than in most cases recorded. The heart was affected in both patients. All the points noted supported the previous observations of Drs. Barlow and Warner, as communicated last year to the International Medical Congress.—The President said it was remarkable that a disease like this should only be recently recognized. He was struck with the fact that the heart should be affected in these essentially chronic cases; was it a general observation that endocarditis accompanied these manifestations?—Dr. Green had seen one case in a boy, sixteen years of age, with acute rheumatism; the nodules were very marked. They were not complained of, but discovered accidentally. The heart disease seemed to develop during the development of the nodule.—Dr. Barlow did not think there was always heart disease in association with these nodules, for some were cases allied to rheumatoid arthritis. But when one finds these nodules one should be on the *qui vive* for heart disease. About a year ago a young man came to the hospital with nodules about the patellæ and elbows. He had been in hospital four months before with subacute rheumatism, but no heart disease. Dr. Barlow sent him home, and, although the temperature did not rise above normal, prescribed salicylate of soda. A mitral murmur developed, so he could say these nodules make one look out for a form of rheumatism apt to attack the heart. The view put forward by himself and Dr. Warner was that these nodules were outgrowths of fibrous tissue, analogous to the simple vegetations found on cardiac valves—i.e., the slow change in the mitral valve which may protect the valve without causing any fibrinous deposit upon it.—Mr. Godlee asked what structure was affected by these rheumatic nodules, for in a case supposed to be ganglion on the palm of the hand there were nodules on the palmar fasciæ. On searching he found many nodules elsewhere, and detected a bruit at the heart.—Dr. Barlow had satisfied himself that these nodules were attached to the deep fasciæ. It had been asserted that the periosteum was their seat; but this is not the case; it is the deep fasciæ, and often the tendons.—Mr. Barker believed he had seen these nodes in a middle-aged woman, be-

tween forty and fifty, suffering from rheumatic arthritis.—Mr. Travers mentioned a case in a patient forty-five years old. It was a severe attack of acute rheumatism, with high temperature. The nodules which appeared on the right elbow and the patella caused some pain; there was no cardiac disease. The nodules eventually disappeared. This case was not benefited by salicin.—Mr. Golding Bird asked whether the nodules were allied to Dupuytren's contraction of the fingers. Some years ago he saw a case of this affection in an early stage in a woman of forty-five; there were nodules on the palmar fasciæ adherent to the skin and tendons. No rheumatic pains. Observed for some months, the nodules gradually diminished under iodide of potassium. They had since recurred. The fingers were not much bent, and under treatment could be straightened.—Dr. Duckworth, in reply, took the opportunity of stating that English literature was much indebted to Dr. Barlow and Dr. Werner for their papers on this subject at the Congress last year. He believed Mr. Parker had examined these nodules microscopically, and found them to consist of delicate fibroid tissue. They come and go quickly, lasting in one of his cases for six months, the longest recorded. As to age, the majority of cases are in young people, but he had seen cases in old people.

MEDICAL SOCIETY OF LONDON.

Congenital Cystic Hygroma.—The Treatment of Wounds.

At a meeting of this Society, held on Nov. 6th, Mr. F. Mason, President, in the chair, Mr. Edmund Owen exhibited two cases of Congenital Cystic Hygroma, and read a short paper on them.—The President was not satisfied that the tumour on the side of the cheek communicated with the cyst beneath the tongue.—Mr. Bryant remarked that the cases were seen in a later stage, and no communication between the larger tumour and the mouth was to be found. He advised enucleation and removal. In its present state the smaller tumour might be taken for a congenital nevus. In three cases he had noticed hygroma to be associated with imbecility.—Mr. Owen, in reply, admitted that perhaps there was no communication between the two cysts in the first case, but he thought they were connected by fibrous tissue. In the second case, he thought the hygroma was degenerated. The difficulties of removal of the cyst in the first case were very formidable.

Mr. Sampson Gamgee then read a paper on the Treatment of Wounds.—The President asked if Mr. Gamgee made any difference in treatment between hospital and private cases.—Mr. W. Adams coincided entirely with the principles laid down by Mr. Gamgee. The exclusion of air and water were the leading features of his own practice. Wounds from which air and water were excluded ran the course of subcutaneous wounds. He presumed that Mr. Gamgee excluded water as favoring decomposition. What did Mr. Gamgee use when wounds required to be washed? The principle of firm support and even compression was unduly neglected in modern practice. Richardson's colloid styptic he used extensively in his own practice, and knew nothing of the kind so valuable.—Dr. Richardson suggested that it deserved to be determined by surgeons what was the precise thermometric indication for taking off the dressing from a wound. What account, in respect to rise of temperature, ought to be made for natural reaction? What degree of temperature should be

considered as necessary to determine interference with the dressing? What time of continued increased temperature should be allowed to elapse before such interference? There ought to be a fair approximative general rule on this subject. Referring to the practice inculcated in Mr. Gamgee's paper, he said that in principle it dated long back. It was a treatment more or less in use ever since Friar's balsam was known as a remedy for wounds. It contained the true secret of Sir Kenelm Digby's expectant non-interfering method; it was the method enforced in a past century by Belloste; it was a method which, in this country, has from the last century into the present held its own. It had sometimes been supplemented by extraneous and fanciful procedures. Sir Kenelm Digby and his adherents had supplemented it by introducing, as an adjunct, the sympathetic powder with which the sufferer was taught to polish the weapon which caused the wound, as if that were a part of the cure; and in our day we had seen it supplemented by procedures which in future times would read, he believed, as equally unnecessary and nonsensical. Mr. Gamgee had brought the practice back to its true physiological bearing by showing that the sustinment of life in the injured part itself was the cause of success in healing, apart from any mysterious local surroundings or imaginary destructive agencies. In cases where there is bleeding from a wound that has been inflicted some time, and from which there is offensive odor, Dr. Richardson agreed with the author that the iodized was more effective than the styptic colloid. He agreed equally in opposing the employment of water for dressing wounds, and recommended for cleansing purposes proof spirit, containing tannin and glycerine, a solution which was at once a good wash and a good styptic. Dr. Richardson concluded by urging that the profession ought to continue on the splendid historic lines that had been laid down for it in the past, and that if, instead of pursuing this course, it allowed itself to be led away by the hypotheses of men, however distinguished, who did not belong to it, and did not understand its practical work, it would go down altogether in fact as well as in estimation.—Mr. Page did not think the thermometer a sufficient index of danger by reason of the various nervous temperaments of the different patients, which determined a rise in temperature in the reaction after a wound. Mr. Gamgee's paper was based on sound physiological principles; but he could not agree with Dr. Richardson's strictures on Listerism, which he thought would always be regarded as an effort to restore natural conditions to the seat of the wound.—Mr. E. Owen corroborated Mr. Page's remarks about the varying degrees to which the temperature might normally rise in different persons.—Mr. Bryant agreed with Mr. Page that Mr. Gamgee's paper was based on physiological principles. He noticed that Mr. Gamgee seemed to advocate light pressure by bandaging, not the firm pressure he formerly recommended. He agreed as to the importance of immobility in wounds of soft parts. Mr. Gamgee had hardly emphasized the advantage of drainage as much as he might have done. To secure free drainage was a most important indication, and caution should be used in dressing wounds in such a manner that free drainage was not permissible. Though not a "spray and gauze" man in any sense, yet he had faith in the action of the drugs known as antiseptics, which obviated the tendency to decomposition induced by water. Mr. Gamgee eschewed water altogether in dressing. He recommended also his principle of letting wounds alone as much as possible. The degree of elevation of temperature was as important an indication as persistence of elevation. Isolated

risers were of little consequence. Persistence after the second or third day was of much consequence.—The President had for many years practiced Mr. Gamgee's method, as a rule in private practice, and occasionally in hospital practice, although this was rather difficult in a hospital imbued with the doctrines of Listerism.—Mr. Gamgee, in reply, said he did not trouble too much about the arrest of bleeding. He shut the wound up as quickly as possible, and under this system he never had secondary hæmorrhage. It was on accurately fitting universal pressure that he relied, not on localized hard pressure. He never sealed wounds without allowing free drainage. The washing of wounds should be as slight as possible; too much was injurious. He could find no difference, physiological or practical, between boroglyceride and glycerinum boracis (B. P.), with an excess of borax. He warmly advocated the study of Dr. Richardson's book on the healing of wounds, and mentioned certain facts showing the influence of mental excitement on the elevation of temperature in surgical cases. Many great operations were accomplished without any rise whatever. He treated private and hospital patients in precisely the same manner. The secret of Mr. Lister's success was the consummate skill and care with which those whom he had educated were trained to carry out their treatment.

Osteitis Deformans.—Ammonia, Chloroform, and Ammoniated Chloroform as Antiseptics.—Cases of Nephrectomy.

At a meeting of this Society held on Nov. 13th, Mr. F. Mason, President, in the chair, Mr. Walsham showed a case of Osteitis Deformans (Paget) in a man, aged fifty-five. The affection of the right leg had been noticed for about five years. The left leg was affected shortly after. The right and left femora, the right radius, and the right clavicle enlarged in the order given about three years later. During the last twelve months the skull had increased in size, and the spine had begun to bend. His height had been reduced from 5 ft. 7½ in. to 5 ft. 5½ in. during the last two years. He had previously enjoyed excellent health, and had been free from syphilis, gout, rheumatism, and injury to the bones. One sister had died of phthisis, and another of cancer of the uterus.—The President asked whether there was any defect of intellect. Mr. Noble Smith inquired whether the urine contained sugar. In a case of a lady, sixty-one years old, he had pursued a tonic treatment in view of defective nutrition.—Dr. Routh had seen a similar case twelve years ago; the anterior portion of the cervical spine being chiefly affected. The patient was an anæmic and ill-nourished child, and death was caused by choking. Defective nutrition seemed to underlie these cases.—Mr. Walsham, in reply, said that the man's intellect was unaffected. The urine had been examined for albumen, but none was present. Iodide of potassium had been given without effect.

Dr. Richardson read a paper on Ammonia, Chloroform, and Ammoniated Chloroform as Antiseptics. The author first recalled attention to his original paper in 1850, on the Antiseptic properties of Gases. He had shown that various gases and vapors, including arseniuretted hydrogen gas and chloroform vapor, acted as antiseptics on fresh animal structures, together with many other æriiform and vaporous agents. He showed two small specimens of lung which were shown in 1850 in illustration of the antiseptic powers of chloroform vapor. The specimens had remained in their bottles untouched for over thirty-two years, and were

still well preserved. He next referred to a paper he had read in 1862 on the antiseptic properties of ammonia, in which he had shown that the vapor of ammonia was one of the most perfect of antiseptics. In further demonstration Dr. Richardson exhibited a specimen of blood which had been drawn from a sheep's neck into an ammoniated atmosphere in April, 1862. It had been enclosed in a well-corked bottle for more than twenty years. It was still perfectly fresh and fluid, and although its microscopical characters were changed it could be made to undergo coagulation on displacement of the ammonia, so that it still exhibited what John Hunter would have called "the final act of life." Proceeding to his present research, the author said that since his last paper he had continued to use ammonia vapor as the antiseptic most convenient, and he had improved upon it in two ways. 1. When a structure to be preserved contained a great deal of fat it was apt, after a few weeks, to become saponified, by which its character was changed. To avoid such change he had used what he called ammoniated chloroform, which was simply chloroform and ammonia vapor combined. By this means much less ammonia was required, and the saponifying process was prevented. 2. It was sometimes important to preserve the color of a substance; to effect this the bottle containing the specimen was charged with common coal gas, as well as with the vapor of chloroform. The coal gas contained sufficient carbonic oxide to maintain the color. Specimens of the heart, kidney, spleen, and the viscera of birds were shown, preserved in these various ways. The advantages were as follows:—1. In making a post-mortem the operator had simply to take with him a jar or bottle well stoppered and ready charged with antiseptic vapor. Into this gas drop the specimens, close them down, and keep them for days, or even weeks. 2. In some forensic cases specimens might be retained in pure ammonia or chloroform vapor in a perfectly sound state during a long investigation. 3. The antiseptic results obtained indicated certain uses of ammoniated chloroform in diseases attended with rapid putrefactive change.—In reply to questions from the President and Dr. Routh, Dr. Richardson said that chloroform would only take up a certain small proportion of ammonia. The solution should be used concentrated. In the case of sore-throat it was administered by inhalation. He feared it would be impossible to use the preparation on a large scale so as to preserve whole bodies. He had it tried on sheep and failed, owing to the gases destroying the tissues. Chloride of zinc and spirit embalmed a body perfectly, but made it too hard for dissection.

Mr. Knowsley Thornton read notes of three successful cases of Nephrectomy by Abdominal Section. The first case was that of a child seven years old, in whom the left kidney was removed by median abdominal section for hydronephrosis, which was probably congenital, as the ureter was only represented by a small fibrous cord. The child made an excellent recovery, and is now strong and well-developed; before the operation she was delicate and puny. The second case was that of a woman aged twenty-six, who dated her illness from her second and last pregnancy. The kidney was much enlarged. The patient was almost in a dying state when admitted into the Samaritan Hospital in February, 1892. Mr. Thornton first operated through the loin, but failed to find by this exploration the cause of the trouble. She improved for a time, but soon relapsed, and he removed the kidney by lateral abdominal section (incision of Langenbüch), and then found it to contain a large number of small calculi or con-

cretions. The bladder end of the ureter was tied and brought out of the wound at its lower angle—an important precaution, as this portion of the ureter was generally diseased and putrid in its interior. The patient made an excellent recovery, and in a letter just received she states that her health is good, and the urine clear and natural. The third case was that of a woman fifty-eight years old, who had been known to have had supuration of the kidney for sixteen years. The kidney had been aspirated several times without relief, and Mr. Thornton decided to remove it by Langenbüch's incision. The operation was exceedingly difficult, owing to the great obesity of the patient and the extensive adhesions. The sac into which the kidney had been converted weighed after removal $4\frac{1}{2}$ lb., and it contained twenty pints of pus. The patient made a rapid and perfect recovery without fever, the only complication being some bronchitis, which was present before the operation, and became more acute for two or three days afterwards. Mr. B. Morison, of Canonbury, reports her present condition as satisfactory. The cause of the mischief was found to be a very small umbrella-shaped calculus, of which the handle was fixed in the opening of the ureter. All the operations were performed under strict Listerian principles, and to this Mr. Thornton attributed in great part the even and rapid recovery of the patients. He pointed out the great advantages of the lateral abdominal incision over the median or lumbar section, and expressed his belief that it could be the operation of the future in nephrectomy. He drew special attention to his method of treating the ureter in these cases, as he thought it of great importance. He considered that these cases emphasized the fact already demonstrated by his ovariectomy practice, that under antiseptic conditions the peritoneum can dispose of considerable quantities of effused material without the aid of the drainage-tube, and without constitutional disturbance, even after the removal of so important an organ as the kidney. The kidney could be more safely and thoroughly explored by Langenbüch's incision under antiseptic management than by the lumbar incision.—Dr. Richardson remarked that the use of iodine, which was an oxidizing agent, destructive of putrefactive products and not a germicide, could hardly be considered as an instance of Listerism.—Mr. H. Morris thought the cases did not bear on the comparison between the merits of nephrectomy and nephrotomy. All these cases were clearly cases for nephrectomy; but in others nephrotomy was the proper course to pursue. In the third case an early exploratory incision might have obviated the necessity for nephrectomy. In the second case, were the small black concretions really calculi or concretions of pus and blood? He had lately made an exploratory incision in the case of a man who had since passed a small calculus. A second exploratory incision failed to reveal a stone; but he believed that one was present; and possibly nephrectomy might be required at a later date. No especial antiseptic treatment was employed in that case, but cotton-wool dressings were used. The wound closed with remarkable rapidity, as it did in a previous similar case of his. He alluded to cases where relief had followed nephrotomy, though no stone had been found, and thought that in these cases the affection was an unduly mobile kidney, which became fixed by adhesions resulting from the operation.—Mr. Thornton, in reply to the President, said he considered silk ligatures more convenient than, and as easily made antiseptic as, catgut. He did not deny that good results might be obtained without antiseptics, but still he held that better results

followed their use. Thus he was able to close his wounds without resorting to drainage. He used iodine when he wished to destroy the products of putrefaction; carbolic acid to prevent putrefaction. He did not intend to deny the utility of nephrotomy, but merely to point out that it was not applicable to these three cases. So far as examination had yet gone the calculi contained crystals of oxalate of lime; their outer coating was probably blood.

OBSTETRICAL SOCIETY OF LONDON.

A MEETING of this Society was held on Wednesday, Oct. 4th, Dr. Matthews Duncan, President, in the chair.

Spurious Hermaphrodite.—Dr. Fancourt Barnes showed a child (living) which presented malformations such as those classified by Sir James Simpson under the title of "spurious hermaphroditism." He could find no trace either of testes or of uterus, but thought the child most likely a male.—Dr. Champneys had, in a somewhat similar case, detected the uterus by examination per rectum.—Dr. Swayne said that there was a specimen in the Museum at Bristol in which the external parts were like those in this case, but the internal organs those of a female.

Hypertrophy of Placenta.—Dr. Herman showed a specimen of hypertrophy of the placenta. It had been removed piecemeal, and a large part left at the patient's house. The portion exhibited weighed more than four pounds. To the naked eye its structure did not differ from that of normal placenta. The child was decomposed when born.—Dr. Robt. Barnes had observed in some cases of hypertrophy of the placenta, dropsy of the placenta, and ascites and anasarca of mother and foetus. Possibly the placental villi were overdeveloped in order to find enough pabulum in the hydræmic blood.

Degeneration of Placenta.—Dr. Champneys showed (for Dr. Murray) a placenta exhibiting fibrinous degeneration in the uterine and calcareous degeneration on the foetal surface. The child was born alive.

On an Obliquely Contracted Pelvis of Unilateral Synostosis.—Dr. Champneys read a paper on this subject. The pelvis was that of a child, aged between seven and fifteen, in which the changes at puberty had already slightly commenced. At this point the left sacro-iliac joint became inflamed, leading to synostosis of part of the articular surface. The left half of the sacrum was dwarfed, and this bone rotated so as to look somewhat to the left. The left half of the pelvis was narrowed, the pubic symphysis driven to the right, and its left half displaced behind the right. But compared with most Naegele pelvises, the outline of the brim was less straight, there was less verticality of the ilium than usual, and there was no evidence of transverse rotation of the left os innominatum on its acetabular axis. The author considered the specimen one of a half developed obliquely contracted pelvis of unilateral synostosis, most instructive in its bearing on the production of the typical pelvis of Naegele.—Mr. Griffith thought that the synostosis was congenital. If so, Dr. Champneys' theory would require modification.—Dr. Champneys thought the joint showed clear evidence of disease.

Transverse Septum in the Vagina.—Dr. Gervis described a case of the above malformation. The patient was aged twenty-two, and menstruated regularly. She sought advice on account of pain in micturition, due to a urethral caruncle. About an inch and a half or two inches from its orifice

the vagina seemed to end in a cul-de-sac, having on either side a pouch, giving at first the impression that there was a double vagina. In the left cornu was a small opening admitting a probe into the space beyond. The hymen was present. The uterus could be felt per rectum. The septum was divided with the thermo-cautery, giving exit to a quantity of brownish mucus. A granular erosion surrounded the os uteri. The caruncle was at the same time removed. The patient did well, and the endocervicitis began immediately to improve when freed from the apposition of retained secretions. The author remarked on the value of the thermo-cautery in lessening the risk of septic infection in such cases.

Case of so-called Imperforate Hymen.—A paper on this subject, by Dr. Matthews Duncan, was read. He was induced to relate the case by three circumstances. 1. There was a remarkable absence of any kind of suffering during nearly the whole time of the development of the disease. The patient had never menstruated nor suffered from any uneasiness in connection with that function until eight months before admission, when she was told by a medical man that she had a lump in the lower belly. Since then she had suffered from irregular aching. The author thought the probable explanation of this was that the uterine body was not distended, for facts showed that dilatation of the uterine body was more difficult and painful than dilatation of the vagina and uterine cervix. 2. The case illustrated the treatment without any injections, which had been the subject of remarks at a recent meeting of the Society. An incision was made by Paquelin's cautery knife. About twenty-five ounces of the usual treacly fluid escaped, about twenty ounces on the following day, and the last of it on the fifth day, in all about fifty ounces. At no time had it any fœtor. No hypogastric pressure or interference with the flow was permitted. A piece of carbolized lint was put to the vulva. The patient made an uninterrupted recovery. He thought the risk of peritonitis was increased by the washing out sometimes practiced. He thought the cautery knife was preferable to any other mode of making the incision, because its wound was not an absorbing surface. 3. The condition of the pudendum, rendering the term "imperforate hymen" erroneous and misleading. The vagina was closed by a membrane upon which the hymen could be seen to have its normal position and relations. He had made the same observation in other cases, and he had seen the hymen present when vagina and uterus were both absent. On these grounds he regarded the view of M. Budin (that the hymen was nothing but the anterior extremity of the vagina) as incorrect.—Dr. Robert Barnes said that in these cases toxæmia arose before the blood was evacuated, from decomposition of the hæmato-globulin in the retained fluid. He had not used injections; they were not called for in all cases.—Dr. Gervis could hardly accept Dr. Duncan's view, that the membrane occupying the area within the hymen was vaginal wall. He thought the variations in shape of the hymen, and the absence of muscular fibres in it, militated against M. Budin's view.—Dr. Carter had had under his care a case similar to that described by Dr. Gervis. He had divided the septum and the patient did well. He thought washing out was meddlesome unless the discharge was offensive or there were symptoms of septicæmia.—Dr. Rogers mentioned a case under his own care. Some pyrexia followed the operation. The vagina was not washed out till a week after the operation, and when this had been done the pyrexia subsided.—Dr. Galabin thought it an important question whether in these cases it was desirable to use in-

jections immediately after an interval or not at all. The danger was greater the higher the atresia was situated. He had known of two cases of high obstruction, in which death had followed evacuation, although no syringing was used. Emmett had published a number of cases, many of them of atresia high up, in which recovery had followed treatment by injections. He generally let the fluid flow for twenty-four hours, and then began antiseptic injections. All his cases so treated had been successful. Perhaps it would be best if a perfectly aseptic condition could be maintained by antiseptic dressings.—The President said that Dohrn had entered elaborately into the developmental histories of vaginal closures. What he (Dr. Duncan) wished to show was that cases with blue, thin-walled bulging between the labia were generally, often erroneously, called imperforate hymen, whereas in many, and also in cases where there was no vagina, a hymen could be distinctly seen.

New Intra-uterine Stem Pessary.—Dr. Swayne showed a new form of stem pessary. It consisted of a perforated vulcanite stem, which rested on an indiarubber band attached to a modification of Greenhalgh's pessary. These were introduced separately, but when *in situ* united by a silk thread. The advantages he claimed for it were that it was easily introduced, kept in place, and allowed uterine mobility, so that it was free from some of the dangers that attend stem pessaries. He should only use stem pessaries when simpler and safer means of treating uterine flexion had failed.—Dr. Heywood Smith asked what advantages Dr. Swayne's pessary had over that of Dr. Wynn Williams?—Dr. Edis thought stem pessaries very dangerous. The position of the uterus was too much regarded, whereas its condition was the chief thing. Numbers of cases of pelvic peritonitis occurred from the injudicious employment of stem pessaries, producing much suffering and not infrequently death.—Dr. Rogers did not think Dr. Swayne's instrument more perfect than that of Dr. Wynn Williams.—The President did not use any kind of stem pessary. He had known of many deaths from them, but he never knew of a case of version or flexion cured by them.—Dr. Robert Barnes thought stem pessaries necessary in some cases. Accidents had occurred from them, but now more scientific instruments had been contrived. He preferred that of Dr. Greenhalgh. He had cured cases of anteversion with stem pessaries.—Dr. Herman had known of a death following the use of one of Greenhalgh's stem pessaries.—Dr. Swayne said that in his pessary the indiarubber supporting the stem was firmer than in that of Dr. Wynn Williams. He had used it many times, always with good results. He had always carefully watched the patient, and withdrawn the stem whenever it gave rise to pain or rise of temperature.

A meeting of this Society was held on Wednesday, Nov. 1st, 1882, Dr. J. Matthews Duncan, President, in the chair.

Interstitial or Tubo-uterine Gestation.—Mr. Alban Doran exhibited a specimen of this condition. The gestation cyst was situated at the right side of the fundus uteri. At the anterior and outer aspect of the cyst the round ligament sprang from it, and the Fallopian tube passed into it, expanding as it did so into a funnel-shaped orifice. At the opposite aspect the cyst bulged into the uterine cavity, and a bristle could be passed from the uterus through the tube into the cyst; the tube being here also dilated into a funnel shape at its entrance into the cyst. The tubal origin of the cyst was thus proved. It had burst at the second month. There was a corpus luteum in the right

ovary. Mr. Doran had examined other cases of the kind in the London museums, and gave an account of them. He remarked on the rarity of the condition, and the tendency to early rupture. Had the abdomen been opened, amputation of the uterus would have been the only practicable treatment. He thought that cases in which development in a supposed hernial pouch of the uterus was suspected were probably tubo-uterine.

Cephalotribe.—Mr. C. E. Jennings exhibited an improved cephalotribe.

Hermaphrodite.—Dr. Chalmers exhibited the genito-urinary organs of a child in which the internal parts were female, while the external resembled those of the male. The clitoris was grooved below, but not channeled.—Mr. Doran said that grooving, and even channeling, of the clitoris was normal in some of the lower animals.—Dr. Fancourt Barnes informed the Society that the child he had exhibited at the last meeting had since died, and proved to be a female.—Dr. Champneys exhibited the genito-urinary organs of a female with extroversion of bladder, described by him in the St. Bartholomew's Hospital Reports. The external genitals were such as might belong to either sex.

Torsion of Cord.—Dr. Chalmers also showed an Umbilical Cord presenting remarkable twisting and narrowing near the umbilicus.

Tumour of Placenta.—Dr. Galabin showed (for Dr. J. C. Roberts) a placenta in which was embedded a tumour about the size and shape of an adult human heart. It was incapsuled, and on the uterine side covered by a complete layer of placental tissue. Near it were several small similar detached masses.

Description of a Kyphotic Pelvis, with Remarks on Briesky's Description.—This paper, by Dr. Champneys, was read. The pelvis, except for slight asymmetry, and a process which the author termed "posterior spondylolisthesis," was a typical kyphotic pelvis. The author criticised Briesky's description, laying stress on the influence of sitting, which, in the kyphotic pelvis, he believed, increased the inversion of the tubera ischii, while in the flat pelvis it increased their eversion; the difference depending upon whether the deformity caused the tubera ischii to be inside or outside the line transmitting the body weight—i.e., the sacro-iliac synchondrosis.

Puerperal Diabetes.—A paper on this subject by Dr. Matthews Duncan was read. The author pointed out the distinction between the slight glycosuria of pregnant and suckling women and real diabetes, with its polyuria and large amounts of sugar. Physicians and surgeons were well aware of the dangers introduced into their cases by complication with diabetes. But the subject of diabetes complicating pregnancy and parturition had attracted almost no attention, and this probably arose from its rarity, which might be accounted for by the disease frequently destroying in women the sexual energies, as it is said to do in man. The author had collected twenty-two cases in fifteen women, and they demonstrated the great gravity of the complication, as respects both mother and child. Of the twenty-two pregnancies (including those ending prematurely), four had a fatal result soon after delivery. In seven of nineteen pregnancies in fourteen women the child, after reaching a viable age, died during pregnancy. In two the child was born feeble, and died in a few hours, making an unsuccessful issue in nine of nineteen pregnancies. The histories showed that diabetes may intervene on pregnancy; that it may occur only during pregnancy, being absent at other times; that it may cease with the cessation of pregnancy; that it may come on after

parturition; that it may not come on in a pregnancy occurring after its cure. They showed that pregnancy may occur in a diabetic woman; that it may be not appreciably affected in its natural progress and termination by the disease; that it is very liable to be interrupted by death of the fetus.—Dr. John Williams thought that these cases were less infrequent than, owing to the fact that the urine was not always examined, was supposed. He had met with four. A trace of sugar in the urine was common, but this was not diabetes.—Dr. Robert Barnes had investigated the condition of the urine in pregnancy as to albumen, urea, and sugar. The occurrence of sugar was physiological, though not constant. Sinéty had shown that sugar appeared in the urine when lactation was suppressed; this was of interest in connection with the normal fatty change in the liver shown by Tarnier to occur in pregnancy. He (Dr. Barnes) drew a parallel between albuminuria and glycosuria during pregnancy. Both were physiological, but might pass the physiological boundary, and then grave accidents ensued.—Dr. Champneys inquired as to the treatment.—Dr. Carter said that the tendency of diabetics to collapse and coma would make us expect danger from pregnancy and labour.—The President said that the terribly fatal complication he had been describing had no relation to normal glycosuria. He thought, with Dr. Williams, that attention having been drawn to the subject, more cases would be published. He could lay down no special rules as to treatment.

On the Treatment of Post-partum Hæmorrhage by Hypodermic Injections of Ergotinine.—A paper on this subject, by Dr. C. Chahbazian (Paris), was read. Ergotinine was the alkaloid of ergot of rye; insoluble in water, soluble in alcohol or chloroform. One pound of powdered ergot yielded three grains of ergotinine. It was indicated in post-partum hæmorrhage due to imperfect contraction of the uterus. The dose for hypodermic injection was five to ten minims of a solution containing one-fiftieth of a grain in twenty minims. This might be repeated if necessary, but more than twenty minims should not be given. This produced strong and permanent contraction of the uterus, acted more quickly than ergot (which was only an extract of ergot), and did not cause local abscesses or indurations. Ergotinine was to ergotine as morphia to extract of opium. It was discovered and prepared by Tanret, of Paris.—Dr. Champneys inquired how long ergotinine would keep.—Dr. Wiltshire suggested that the hypodermic injection of ether might with advantage be combined with that of ergotinine.—Dr. Brunton asked how long ergotinine took to act.—Dr. Chahbazian said that uterine contraction usually came on in from two to five minutes after the injection of ergotinine. He could not say how long ergotinine would keep.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.

THE first meeting of this Society was held on Friday, October 6th, at the West London Hospital, Hammersmith. The President, Dr. Hart Vinen, was in the chair, and over eighty-three gentlemen were present.

The President delivered an inaugural address, in which he thanked the members for the honor they had conferred upon him by electing him their first President, and congratulated them on the large number of practitioners who had already joined their ranks, which augured favorably for

the future progress of the Society. After alluding to the numerous Societies which exist for the prosecution of scientific pursuits, and the value of their labors to the general welfare of mankind, he urged the members to look to science as the best aid to the successful practice of their profession, and as not without its moral results. "For if the suggestion of Newton, that in proportion as natural philosophy is improved in its various branches, the bounds of moral philosophy will be enlarged also—if this be true, as it undoubtedly is, we may point to the labors of our scientific men as not only serving to extend the boundaries of our intellectual horizon, but as exercising a refining and humanizing influence over man's moral nature. But there is another light in which we may regard such societies as this, I mean their social aspects. The daily routine of professional duties too often restricts medical men to a very limited orbit, and furnishes them with few occasions for friendly intercourse with their brother practitioners. Here they have opportunities of meeting periodically on common ground, of exchanging opinions on professional and other topics, and by other men's experience enlarging and correcting their own. No remedy is so effectual for healing professional animosities as frequent intercommunication; and if I were asked to prescribe a panacea for their prevention, I should recommend an occasional dinner at the Star and Garter. Some may think this view of the matter savors too much of the sensual, but the periodical recurrence of such a social reunion would, perhaps, be more productive of good results than the strictest code of medical ethics." Dr. Vinen then alluded to the fact that more than twenty years had elapsed since he had filled the presidential chair of another medical society, and referred briefly to the most prominent changes which had taken place during the interval, especially dwelling on the germ theory of disease, which recent researches had done so much to establish, and the benefits which resulted to public health from the advance of sanitary science, in which he claimed for the medical profession the honor of being the foremost workers.

Dr. Burney Yeo then delivered the address.—Dr. Thudichum said he was much interested in Dr. Yeo's paper, though he did not agree with him. There was no proof that the bacteria were destroyed by his process. Those who had examined the expectoration of a phthisical patient and observed the bacilli present in it must have been impressed with the awful nature of the disease; the incalculable number present in the organ seemed to him to render the question of total destruction mathematically impossible. Dr. Yeo admitted that advanced cases were not suitable for this treatment, but he thought that there was no specific which did not cover all cases. He would ask how could these antiseptic inhalations reach the brain, or heart, or any other organ (except the lungs) which might happen to be the seat of tubercular disease?—Dr. Alderson thought that great benefit was to be derived from the use of the respirators, and was most certainly ready on this, as on other points, to reiterate the President's cry for "More light."—Dr. Rayner also endorsed Dr. Yeo's theory.—Dr. Browne wished to know how long it was necessary to wear the respirator at a time.—Mr. Jack was of opinion that whether the bacilli were destroyed or not, the process, in whichever form adopted, put the patient into a condition calculated to prevent a nidus being formed for the bacilli.—Dr. Thorowgood had no great experience on the subject, but he had most certainly noticed great improvement in those cases which he had so treated. He was accustomed to

order the respirator to be worn for an hour in the morning and evening; he found it promoted expectoration. Of the various antiseptics he himself preferred creasote. Sea air as obtained in a voyage was, too, he thought, most efficacious in the early stages of the disease; later on, it seemed to do more harm than good.—Dr. Yeo, in reply, said he did not wish in the remarks he had made to dogmatize in any way, he was only anxious to show that the theory he had been laying before them had a scientific basis. He must say, in answer to Dr. Thudichum, that he was unaware of his having used the expression "specific;" it was not his custom to use the word, and he failed to see anything detrimental to his theory in the fact that advanced cases were not suited to the treatment. As regards the alarming number of bacilli pictured, he would simply suggest that if Mr. Lister had frightened himself about the number of organisms to be encountered there would never have been any such thing as antiseptic surgery. The advantage of the respirator, as suggested by himself, consisted in its lightness and comfort in wear, in fact to its not being a muzzle; his patients wore theirs as long as possible during the working day, it being only necessary to remove it while eating or drinking. He agreed with Dr. Thorowgood in preferring creasote, but he had used eucalyptus and pinewood oil with great advantage, though the latter was to some rather irritating. He saw no reason why still more direct treatment should not be attempted, and he hoped soon to try the effect of injecting by the long needle of an aspirator, a small quantity of bichloride of mercury.

Mr. Saville Kent and Mr. Baker showed specimens of Bacilli, Bacteria, etc.

A meeting of this Society was held on Friday, Nov. 3rd, and was devoted to clinical cases. Dr. Hart Vinen, President, was in the chair, and some forty-five members were present. The principal feature of the evening was the exhibition of three cases of Charcot's joint disease.

The first case was shown by Dr. Atkinson. Besides the usual phenomena of locomotor ataxy, the left shoulder-joint was seriously affected. Some three months after the first symptoms were manifested this joint became swollen till it measured thirty-nine inches in circumference, without any pain or inflammation. At that time (some ten years after) the joint was not enlarged, but there was marked prominence of the acromion process and flattening of the deltoid, and on examination the head of the humerus was distinctly absent, having been entirely worn away, so that the arm could be thrown about in any direction, as if it were a flail. Dr. Atkinson said that the pathology of the joint affection appeared to be some degeneration or disturbance of the trophic nerves supplying the bone leading to the defective nutrition of the osseous tissue, and this might also cause the spontaneous fractures described by Dr. Weir Mitchell as sometimes happening in patients with this disease.

Mr. Edwards, in bringing forward the second case, said that here too the left shoulder was the special joint affected. When the patient first came under his notice some twelve months ago there was a large effusion under the pectoral muscles (not in the joint itself), which was said to have come suddenly a few days before after lifting a weight; he at first thought it must be a hæmatoma, and aspirated it, drawing off some ounces of reddish fluid. Soon after the swelling recurred in the joint itself, in moving which distinct crepitation could be felt, and the head of the humerus

could be easily dislocated, showing that the head of the bone was partially absorbed. With regard to other symptoms, the patient had experienced the "lightning pains," his pupils were contracted unequally, and this patellar tendon-reflex was modified, but not absent.

Mr. Keetley exhibited the third case, in which the symptoms of ataxia as well as joint affection were well marked. He remembered seeing Mr. Edwards' case before, and thought then that there was no ataxia present, but was not aware if further symptoms had been developed since.

A discussion followed in which Dr. Thudichum said that locomotor ataxia was accompanied with a change in the nervous centres termed amyloid (first described by Virchow). Granules were deposited, which after treatment with dilute sulphuric acid and iodine became blue and appeared like iodized wheat-starch granules. It had been said that amyloid matter was albuminous, but that was erroneous. Some amyloid is a starch-like body, and no doubt derived from the decomposition of some of the cerebrin bodies, of which the brain and nerve tissues contained more than 4 per cent. This decomposition set free a sugar cerebrin, all of which can be reduced by losses of water to the amyloid matter. The deposition of this matter in any part of the nerve tissue, particularly the spinal marrow, produced all the varied symptoms shown in these cases.

Mr. Potter next showed a patient, aged sixty-six, who, three years ago, whilst engaged as a laborer, was struck on the occiput by a falling wall, and the cervical spine was forcibly flexed. He was rendered unconscious for two days, but indistinctly remembered some one pulling upon the head and twisting it from side to side. Loss of power and sensation of the right arm and leg was noticed by the man when consciousness returned. He kept his bed for four months, an immovable apparatus for the head and neck being applied. One month after the injury the neck was noticed to be swollen, and increased till one year ago. No history of syphilis or rheumatic arthritis. A swelling in the median line at the back of the neck, extending from one inch below the external occipital protuberance to the sixth cervical spinous process, measuring about four inches in diameter. The trapezii appeared to be incorporated with the swelling on each side. It was hard, dense, with no discoloration, not tender on pressure, and with no evidence of deep fluctuation. The manubrium sterni and upper three costal cartilages and larynx were abnormally prominent; the chin almost touched the sternum. The posterior boundary of the pharynx could hardly be reached with the tip of the finger. The patient complained occasionally of dysphagia and dull aching pain in the swelling. Mr. Potter thought the nature of the tumour obscure; the history, however, tended to show that the swelling was due to callus, which, in this case, was exuberant, owing to the movements of the neck being difficult to restrain. Whether the spinous processes with a portion of the laminae were fractured without much interference with the cord and nerves it was difficult to determine.—Mr. Keetley said that after careful examination of the case he could not help thinking that the patient's injury had been rather under-estimated. It appeared to him that there was a general bending backwards of the cervical region, and that the bodies of the vertebrae had been forcibly compressed, leading to fracture; the deformity was owing to a condition similar to that met with in Pott's curvature of the spine.—Mr. Potter, in reply, said although this was possibly the case, the absence of callus deposited on the anterior parts of the bodies was a fact to be borne in mind.

Mr. Lunn exhibited the Brain of a patient who had died after a third attack of Apoplexy. The case first came under his notice in the second attack, which was one of right hemiplegia, and aphasia, and from these partial recovery, when the third seizure took place. It was observed that the temperature rose from the commencement of the seizure till death from 99° to 106° F., and after death there was a further rise to 108° in the rectum. Mr. Lunn had noticed this rise in temperature in three other cases of apoplexy. On examining the brain, the right ventricle was found distended with a dark soft clot and fluid blood, and the optic thalamus was extensively lacerated. On cutting through the left corpus striatum, a cyst about the size of a walnut, lined by a smooth yellowish-brown membrane, and filled with clear yellowish fluid, was found.

Dr. Clippindale brought forward a case of Spontaneous Dislocation of the Sternal end of the Clavicle consequent upon lateral spinal curvature, due to dislocation of the hip, and observed that he could find no similar case on record, and only one case of spontaneous dislocation of the sternal end of the clavicle.

Mr. Keetley lastly shewed a case of Arterial Embolism. When the patient was admitted into the hospital in the month of August, pulsation could be felt in both external iliacs, and in the right but not in the left femoral artery; strongly in the right tibials, feebly in the left. In the situation of the left common femoral was a slight swelling tender to touch. Temperature in both legs about the same; no signs of cardiac disease; had shortly before admission been so "low-spirited" as to lead his friends to fear an attempt at suicide. He was put on iodide of potassium (ten grains) and aromatic spirit of ammonia (half a drachm) three times a day. He steadily improved; pulsation gradually returned in the left femoral and grew strong in the tibials, while the tenderness over the common femoral diminished; but the oedema of the left leg, which had at first been scarcely perceptible, increased considerably till the difference in measurement was two inches. His spirits also brightened up, and he felt quite well, strong, and cheerful.—Dr. Pope asked if the patient were in the habit of flexing his leg.—Mr. Lloyd also wished to know whether there had been typhoid symptoms, or whether the rectum were loaded.—Mr. Keetley answered the last two questions in the negative, and said that the man's employment was that of a machinist.

EPIDEMIOLOGICAL SOCIETY.

A MEETING of this Society was held at University College, Gower-street, on Wednesday, November 1st, Dr. George Buchanan, President, in the chair.

Dr. Norman Chevers read a paper on the Sanitary Defects of the Site of London and its Environs, of which the following is an abstract. He was of opinion that notwithstanding all that modern land and town drainage had effected in the way of improvement, the most prevalent and worst diseases of the United Kingdom are due to the survival of thousands of acres of unreclaimed marsh land, and to the presence of thousands of miles of sewers, drains, and ditches, which retain, exhale, and exude as much as they void. The Celtic and Roman founders of London chose their position mainly because it was defensible in war, and without any knowledge of the laws of malaria. The superficial geology of London may be represented by an oval cup of London clay and brick earth, extensively traversed and margined by marsh alluvium across the longer diameter, of which

irregular heaps of more or less sandy gravel form a broken line of slight elevation. The greater part of Roman London was seated on good building ground. Originally marshes or swampy soil surrounded the entire land aspect of modern London, with the exception of an isthmus on the north-west. The whole line of the northern hills had, at its foot, oozy soil, into which the drainage of the uplands sank, to be only partially carried off by streams. The City was also protected on the north side by Finsbury and Moorfields, formerly a vast swamp. To the east London is bordered by the extensive marshes of the river Lea and the Thames, and east of these marshes extend vast tracts of the Essex and Kentish marshes, sixty miles to the sea. The Kentish marshes extend also to the south border of London, and those parts of the City now bearing the names of Bermondsey, Southwark, and Lambeth, were especially notorious, almost down to the present time, for the occurrence of ague, dysentery, and remittent fever, amongst the inhabitants. Originally the marshes westward were as injurious to the public health as those to the east; Westminster was almost an island even in Queen Elizabeth's reign, and St. James's Park was liable to be flooded up to 1682. Even now South Belgravia is threatened with inundation from the Thames. Northward of this part of London the ground is more or less elevated, and gravel and clay are found more abundant. Dr. Chevers next pointed out that much of the ground upon which houses are now, and have been for centuries, built consists of made earth; for instance, that in Finsbury-fields in 1549 one thousand cartloads of bones were deposited, and upon this was laid the soilage of the City, all of which has long since been built over. He then briefly alluded to the significance of the Anglo-Saxon word *ey* in many of the place names of London, as showing that the localities were originally paludal; and mentioned a few facts which indicated the great prevalence in old times, and as late as the end of the seventeenth century, of dysentery and intermittent fever in London. Dr. Chevers urged the necessity for a great national movement for the reclamation and utilization of marsh lands near London, and that a Royal Commission should be appointed to inquire into the whole question and adequate funds raised. He believed trees might be planted on the Essex and Kentish marshes which would in a few years mitigate the severity of the east wind; that all kinds of manufactures not requiring night service might be carried on there; and that market gardens and reservoirs for fish for markets might also be made, and thus render the lands not only more salubrious, but more valuably productive than they are at present. He concluded by saying that every landlord should be under legal obligation to satisfy his tenant whether the site of his house had been a marsh, a brickfield, a burial-ground, or a plague pit; whether the house is built upon concrete, and whether there are disused cesspools near the building. In the discussion which followed, the President, Sir Joseph Fayrer, Surgeon-General Hunter, Surgeon-Major Don, Dr. Thorne, Mr. Shirley Murphy, Dr. Henderson, Mr. Long, and Dr. Balfour took part.

CAMBRIDGE MEDICAL SOCIETY.

At the meeting on Oct. 6th, 1882, Professor Humphry, President, in the chair, Mr. Wherry related a case of Complete Inversion of the Uterus. The patient was a woman who had been delivered two days previously of a healthy male child, which was born rather suddenly and with a short

thick cord. She was given twenty minims of liquid extract of ergot after delivery, and shortly after this had a pain, and there was protruded from the vagina what at first appeared like the head of another child, but which proved to be the inverted uterus, with the placenta adherent. There was not much hemorrhage. The medical attendant detached the placenta and endeavored to replace the uterus by his hand, but he was obliged to desist, owing to the great softness of the uterine walls and the collapsed condition of the patient. Two days later, when called in, Mr. Wherry found the uterus completely inverted. Ether was administered, but it was quite impossible, owing to the doughy softness of the fundus, to replace the uterus with the unaided hand. Accordingly a large rubber drainage-tube was inflated to about the size of an egg at one end and ligatured. The hand, in the form of a cone, was passed into the vagina, and the finger tips, pressed against this air pad, were in no danger of lacerating the walls of the uterus. Half an hour's pressure, first with one hand and then with the other, against the most prominent part of the fundus, at length reduced the uterus, leaving the dilated tube in the cavity. The string was then cut and the collapsed tube withdrawn. The replacement was not by a jerk, but gradual, and to be compared to the relief of a paraphimosis; it was evidently effected by squeezing fluid out of the oedematous tissues of the uterus. The patient, after three days of fever and pain in the body, made an excellent recovery.—Dr. Ingle said that complete inversion of the uterus must be a rare occurrence if the figures given in some text-books were correct. Braun states that of 150,000 births in the clinics respectively under the charge of Spæth and himself, not a single complete inversion had come under their notice. There was one case in 190,000 confinements at the Rotunda; but much doubt had been thrown on these statements by later writers. He had not seen a case of complete inversion, but remembered one of partial, in which the patient died very quickly from hemorrhage. Might not such an accident arise from a mal-condition of the walls of the uterus brought on by constitutional disease; by previous imperfect involution; or from irregular contractions; the normal rhythmical movements of the muscular coat being interrupted from either of the above causes? Would not restoration be better effected by the free use of chloroform before an attempt at replacement? It had been shown by Dr. Hewitt how more or less inversion may occur days after labour from incautious exertion. Is it not likely that partial inversion takes place much oftener than is supposed, but is altogether overlooked, leading to grave subsequent interruptions of the monthly health?

Mr. T. Lucas (Cambridge) produced a specimen of Membranous Cystitis from the bladder of a woman he had attended for this condition. The patient was twenty-eight, and was delivered of her third child in 1881. She had phlegmasia dolens after the birth of her second child. On the ninth day after her last confinement she had pain over the hypogastric region and retention of urine. In a few days she had feverish symptoms and a temperature of 103°, pain in the left groin, followed by swelling of the left thigh and leg. The use of the catheter was required for twelve days, after which time the leg was well. The urine contained mucus and albumen. Ten days later there was complete and sudden retention of urine, and on passing the catheter an obstruction was met with which proved to be a piece of membrane blocking the urethra. This was withdrawn in pieces, and then a quantity of ropy urine escaped through the catheter. A few days later a piece of

membrane about six inches by four was removed, and subsequently another piece, ten by twelve inches, came away. Ten days later the woman had entirely recovered. The membrane consisted of a fibrillated network, in the meshes of which were enclosed leucocytes, granular matter, and crystals of phosphate of lime, and seemed to be a cast of the mucous surface of the bladder.—Dr. Humphry said he had, in the case of a young woman, dilated the urethra with his finger and removed a large amount of mucus membrane covered with phosphatic deposit; and observed that the mucus membrane of the bladder had hardly any secretion and very little glandular substance. In cases where the whole mucus membrane sloughed off it seemed due to a process called by Leuchars necrosis of the membrane.

Dr. W. A. Smith (Newport) related a case of Lateral Sclerosis. The patient, a man, aged forty-four, eighteen years previously had sprained his back by lifting a heavy weight, and had for the last two years been getting more feeble and stiff in his back, and had pains in his legs. He was removed to St. Walden Hospital, and while there the chief symptoms were general rigidity of back and legs, excessive knee-jerk and ankle clonus, slightly impaired sensation, especially in left leg, and considerable wasting, also deep-seated tenderness at lower part of spine on pressure, and pain extending to the groin. There was also a general shaky condition of head and lips, and fibrillary twitchings and stiffness about muscles of the neck. He was treated with iodide of potassium, blisters, and actual cautery. Dr. Smith considered the case one of lateral sclerosis, with very slight, if any, disease in the posterior columns, and that the stiffness of the muscles of the head and neck might possibly point to some patches of sclerosis high up in the cord. He discarded the notion that there might be any deep-seated caries, but thought these pains might be due to pachymeningitis of the cord. This, too, would satisfactorily explain the lateral sclerosis, because primary sclerosis is very rare, the disorganization usually following a focal lesion as a focal myelitis.—Dr. Bradbury mentioned a case he had treated in hospital, and which had rapidly mended under the use of iodide of iron and the battery, after the failure of other remedies, and another case in which ankle clonus and knee-jerk had existed and in which iodide of potassium had failed, but which had, after two months, nearly recovered under the use of syrup of the iodide of iron and quinine.—Dr. Paget referred to a case under his care where apical disease occurred in a man accustomed to violent exercise in cricket, skating, etc.

Dr. Bradbury narrated a case of Cerebellar Tumour. The patient was twenty-two years of age, had never had syphilis, and there was no history of injury or fits. He had been subject for years to neuralgia in face and forehead, and for a month, before coming under Dr. Bradbury's care, to neuralgic pain on the top of the head and the occipital region. Sleep was disturbed, and the pain had exacerbations every few minutes, always increased at night. Had vomited at first, but that abated. There was an expression of suffering in the face (in May), pain in occipital region, but no signs of disease in the thoracic or abdominal organs, and the optic discs were normal. In June he had had considerable relief from pain and had taken belladonna and quinine, and afterwards iodide of potassium. During the next month he had occasional sickness and pain varied in amount. In July he lost control over his rectum, but not over the bladder. He was unable to walk without help, but when assisted took short hesitating

strides with some tremor of legs. Gait unaltered when eyes shut; has had no tendency to bear to one side more than the other in walking. Sensation unaffected. Patellar reflex slightly exaggerated. No ankle clonus. In August there was no vomiting or diarrhoea, but a good deal of headache, though there was progressive weakness and emaciation. On September 9th he died rather suddenly, after having got steadily weaker. The pain had diminished and he had been getting drowsy, and had lately lost the control of his sphincters. The autopsy revealed a tumour in the right hemisphere of the cerebellum, as large as a hazel nut, consisting of a white cheesy mass of irregular shape, surrounded by softened cerebellar structure of a reddish color with a few hæmorrhagic spots. The rest of the lobe was softened and altered. In the left lung was a small cavity at the apex, surrounded by caseous tubercles, and there were miliary tubercles scattered in the lower lobes of both lungs. Dr. Bradbury remarked that in this case two of the symptoms of an intracranial growth were present at an early stage—viz., vomiting and cephalalgia; another symptom, double optic neuritis, was absent throughout, as sometimes happens in cases of even large intracranial tumours. As there was no optic neuritis or atrophy, so the sight was not affected. The diagnosis of cerebellar tumour was based on the seat of pain, which was chiefly occipital, and the peculiar gait of the patient, which was like that of a drunken man—a swaying of the trunk during progression from front to back and from side to side. This has been called the "cerebellar reel." Vertigo was not a prominent symptom. During the latter part of his illness the patient lay in a peculiar apathetic condition, but answered questions on being roused. There was no complaint of stiffness about the back of the neck. The patellar tendon-reflex was slightly exaggerated. The presence of tubercles in the lungs showed the cerebellar tumour to be of a tuberculous nature.

MIDLAND MEDICAL SOCIETY.

THE first ordinary meeting of this Society was held in the Birmingham Medical Institute on October 25th, Dr. Malins, president, in the chair.

Mr. Furneaux Jordan exhibited a specimen of a Suppurating Node, situated on the upper portion of the diaphysis of the tibia. The child was the subject of inherited syphilis, and its general condition was such as to necessitate removal of the affected limb above the condyles. The subsequent recovery was rapid.—Mr. Chavasse thought that the bone disease of inherited syphilis originated in the medulla of the diaphysis, as suggested by Waldeyer, and was not an osteocondritis commencing in the cartilage.

Dr. Malins showed a new form of Uterine Sound of ingenious construction.

Mr. Chavasse exhibited a specimen extracted by literal lithotomy from the bladder of a man forty-seven years of age. It consisted of three inches of solid indiarubber tubing thickly coated with phosphates. The patient had introduced the tubing to relieve himself of scalding during micturition.

Mr. E. L. Freer showed a portion of the Cranial Vertex, about two inches square, devoid both of aponeurosis and dura mater, which had been blown off a boy's head by the bursting of a small pistol. The weapon contained neither bullet nor foreign body. Death was instantaneous.

Mr. Furneaux Jordan gave the details of three cases of Gunshot Injury to the head, in which recovery took place with retention of the bullets.

The first was that of a man who shot a woman through the ear, and afterwards himself, with a fatal result. The bullet entered the woman's external auditory meatus, and passed into the petrous portion of the temporal bone. With difficulty a portion of the bullet was extracted by one of the three surgeons who met in consultation, but it was deemed advisable to make no attempt to interfere with the remaining part. The patient made a perfect recovery. The second case was that of a middle-aged clergyman and magistrate, seen in association with Mr. Walker, of Upper Gornal, who was deliberately fired at three times. The first bullet entered behind and above the right mastoid process and penetrated to the interior of the cranial cavity, as evidenced by an escape of cerebral matter through the wound. The second bullet entered the mouth, passing upwards and perforating the hard palate. The third bullet entered the side of the neck, and probably lodged in the body of one of the cervical vertebrae. On receipt of the injury the patient did not fall, although a certain amount of shock resulted. When examined by Mr. Jordan the wounds were dry and covered with blood-clot, so no attempt was made to dislodge the bullets. With care and quietude a complete recovery resulted, and now, after three years, a hard substance can be felt along the floor of the right orbit. This is considered to be the second bullet, which has worked its way into the orbital cavity, where it gives rise to no inconvenience. The third case was that of a gentleman who was seen in consultation two days after an attempt had been made at suicide. The pistol had been pointed just above the right zygomatic arch, and the bullet had probably passed towards, and fractured, the roof of the right orbit. The brain matter was found outside the wound. There was complete unconsciousness and an enormous sanguineous extravasation around the orbit. The aperture of the bullet was small and covered with a dry blood-clot. Expectant treatment was adopted; consciousness gradually returned. The extravasation subsided, and ultimately recovery took place. Mr. Jordan agreed with the general rule that no attempt should be made to extract bullets which had perforated any of the great cavities of the body unless they can be easily and certainly reached, the retention of the bullets giving the patient a far better chance of life than that afforded by strong or prolonged efforts to extract them. To trephine in such cranial injuries was held to be a dangerous expedient. If ever needed it should be only with full Listerian precautions. If any foreign body is driven into the wound the prognosis is rendered more grave, but pieces of bone were not regarded as such a bad complication as were portions of clothing.—In the discussion which followed, Mr. Greene gave an account of an attempted suicide in which the bullet was found quite flattened out, lying in contact with the parietal bone.—Mr. Eales narrated the case of a man, aged sixty, who, in the dissecting-room at Queen's College, was found to have a bullet encysted in the mastoid process, and impinging upon the lateral sinus. On inquiry it was found that the man was an old soldier who had served in the Crimea and also in the Indian Mutiny. The wound had been received many years before death.

Mr. Priestley Smith, who had had charge of a hospital in the Franco-German War, and many hundred cases of bullet wounds, did not see or hear of any instance recurring in which the cavity of the skull had been opened. Such patients generally died before they could be sent back from the front.—Mr. Freer, Mr. Bennett May, Mr. Jordan Lloyd, and Mr. Harman also made remarks upon the paper.

Dr. Saundby read a paper on the Treatment of

Epilepsy, in which the following points were insisted on:—1st. The value of combining the bromides of potassium, sodium, and ammonium, as recommended by Professor Brown-Séquard. 2nd. The advantage of adding tincture of digitalis and sometimes theine to the mixture to counteract the depressing influence of the bromides. 3rd. The utility of zinc as an adjuvant in the treatment. 4th. The successful use of borax in some cases of obstinate epilepsy, of which two illustrative cases were given. 5th. The value of theine or caffeine and nitro-glycerine in the treatment of epileptic vertigo.—In the discussion which followed the paper, Mr. R. Smith, Dr. John Greene, Mr. J. H. Palmer, Mr. Lloyd, Dr. Robinson, Mr. Eales, and Mr. Chavasse took part.

NORWICH MEDICO-CHIRURGICAL SOCIETY.

THE first meeting of this Society was held on the 7th inst. at the Norfolk and Norwich Hospital, Dr. Barnes (Eye), the President, in the chair.

An exhaustive retrospective address of the work done during the past year was read by Mr. T. L. Lack.

Mr. F. C. Bailey (Norwich) exhibited a specimen of a Double Fœtal Monstrosity, united apparently by the sternum; the specimen was reserved for dissection in order to demonstrate the bond of union.

Dr. McKelvie (Cromer) exhibited a fibro-sarcoma of the neck removed post mortem; the tumour had existed about fifteen years; it measured 32 in. by 30 in., and weighed 17½ lb.

Editorial.

SIR THOMAS WATSON, BART.

FULL of years and of honors, the greatest English physician of the present century has at length gone to his rest. We have elsewhere given some details of Sir Thomas Watson's distinguished career, and we have traced his progress from the Grammar School at Bury St. Edmunds to the unquestioned headship of the medical profession, a position which for many years he occupied with singular honor and dignity. As he was honored by being so highly placed amongst his professional brethren, so his exaltation may be said to have reflected honor upon the profession, whose members so highly and so universally appreciated the high qualities of their revered head.

The last occasion on which Sir Thomas Watson attended a meeting of the Fellows of the College of Physicians was in the spring of the present year, when Sir William Jenner was for the second time elected President. In the absence of the senior censor, the senior Fellow present was called upon, in the usual form, to deliver to the re-elected President the insignia of his office and to administer the formal oath. When Sir Thomas Watson got up to walk towards the President's chair, the whole of the assembled Fellows rose as one man to show their respect and affection for their venerable ex-President. The respectful feeling which was then so touchingly and spon-

taneously displayed by the assembled Fellows of the College of Physicians is shared by the entire profession, who will feel as a personal loss and sorrow the removal of one whom they have so long been accustomed to regard as their most distinguished member. What, then, are the qualities which have gained for this great physician the respect and affection of all who have had the privilege and the happiness of knowing him? It is the rare and happy combination and balance of great intellect with the highest moral qualities which constitute the truly wise and good man. In this sense an eminent living physician has spoken of Sir Thomas Watson as the wisest man whom he had ever known; and a near relative describes him to have been the most unselfish of men. His own lectures and public addresses may be looked upon as giving the best and fullest illustration of the illustrious physician's mind and character. What student or practitioner of medicine can read thoughtfully that well-known and often-quoted introductory lecture in which, in terms of solemn and lofty eloquence, are set forth the privileges and responsibilities of those who enter the profession of medicine, without being led to form a higher estimate of his calling? without being inspired by the desire to act up to those lofty principles which the earnest teacher endeavors to infuse into his pupils? And that he taught no less by example than by precept is known and gratefully acknowledged by thousands who have had the privilege of his acquaintance. He was himself a living impersonation of the principles which he so eloquently expounded in his lectures. And, withal, he was modest and unassuming, as becomes a truly great and wise man.

THE MOVEMENTS OF THE BOWELS IN HEALTH AND DISEASE.

PERHAPS there is no function of the body which plays a more important part in various morbid conditions of the abdominal viscera than the movements of the bowel; and certainly there is none which, in its pathological relations, has received less experimental study. Uncertain inference from clinical symptoms is almost all that physicians have had to depend upon in their diagnosis, and in their endeavor to alter by treatment that which they assume to be present. As an instance, we may adduce the difference of opinion which has existed and still exists among distinguished authorities on the question whether there ever is, in morbid states of the bowels, what has been mis-called an antiperistaltic action—a question of great importance in many acute disorders.

Thanks to the well-directed energy of Nothnagel, and so far as animals can furnish it, we have now some definite knowledge. He has made a series of experiments to ascertain by actual observation what modifications the intestinal movements undergo in morbid states. The experiments (de-

scribed in the *Deutsche Zeitschrift f. Klin. Med.*) involved no suffering to the animals concerned. All were kept insensible by ether—dogs and cats by inhalation, rabbits by subcutaneous injection; and all were killed by division of the medulla oblongata as soon as the experiment was over, and before the return of consciousness. The method employed was that of Sanders and Van Braam Houckgeest, of keeping the animal, with abdomen opened, immersed, with the exception of the head, in a one-half per cent. saline solution, at a uniform temperature of 100-2° F. Under these circumstances, as the originators of the method pointed out, rest is the rule in most parts of the bowel, with the exception of the duodenum. Now and then, at rare intervals, there is a gentle peristaltic movement in the small intestine, and local irritation causes only a local effect, without producing any trace of general peristalsis. But the condition is changed at once by the presence of a quantity of gas and liquid distending part of the bowel. This is immediately moved forwards by a stormy peristalsis, a circular contraction behind it pushing the distended portion onwards to the cæcum. Sometimes, however, the movement suddenly stops, to go on again after a brief pause. It is distinctly analogous to the sudden temporary cessation of griping pain, which is familiar to most people. Nothnagel can discover no cause for it, except a sudden inhibitory nervous influence, which its aspect indeed suggests.

As regards the first fundamental question—the occurrence of antiperistalsis—Nothnagel entirely corroborates the statement of Engelmann, that the intestinal contractions may take place either upwards or downwards. But the last-named observer, experimenting with the intestine exposed to the air, was in error in assuming that peristaltic action, upwards or downwards, was set up by any local irritant. When the bowel is preserved from the air by the saline solution, local irritation causes a local constriction, if the bowel was previously at rest. Moreover, Nothnagel concludes, from a series of sixty observations, that antiperistalsis never occurs in the normal uninjured intestine so long as no pathological influences are brought to bear upon it.

The effect of injections into the rectum was next investigated, the injections being of indifferent or irritating liquid, tinted with carmine so as to show how far it was sent up the intestine, and post-mortem examination subsequently showed whether it had been carried higher by any movement of the intestine itself. A small quantity of warm water (from two to five cubic centimetres) had no effect; it remained in the rectum until ejected by a contraction, or until it was absorbed. A somewhat larger quantity distended the rectum, but seemed to excite little peristaltic action, some of it escaping in consequence apparently of the elasticity of the bowel. Iced water caused constriction, which passed a short distance upwards so as to move the

injected fluid up from five to twenty centimetres. Olive oil gave a similar result. Of greater significance, however, was the effect of a strong solution of chloride of sodium. A small quantity, three to five cubic centimetres, passed up, by the force of the injection, about ten centimetres. In a few minutes, however, the colored liquid was carried upwards by a distinct ascending contraction, and the antiperistalsis gradually carried it, together with a mass of faeces, as high as the caecum. Sometimes the antiperistalsis took the form of a series of circular constrictions, especially marked at the highest part of the column of liquid. Besides this, descending contractions occurred in the lowest part of the rectum. Similar results were obtained with injections of concentrated solutions of nitrate of potash and bromide of potassium, and weak solutions of sulphate of copper.

Nothnagel found that the needle of a hypodermic syringe could be passed through the wall of the small intestine without exciting local contraction, and the minute wound immediately closed without allowing the escape of the intestinal contents. Injections of chloride of sodium were found invariably to cause contractions which passed upwards as well as downwards. In a case of ileus in the human subject he found that chloride of sodium solution has evidently the same effect as in animals, since a small colored injection into the rectum was found after death to have passed upwards some distance above the caecum. The fact may possibly prove of great practical importance in the treatment of intestinal obstruction. The injection of indifferent fluids of the temperature of the body had as little effect on the small intestine as on the rectum. The conclusion from this series of experiments is that when the intestine is under normal conditions, or contains only unirritating contents, the peristaltic contractions occur only in the direction from the stomach towards the anus. If, on the other hand, the contents of the bowel consist of an irritant substance, the stimulant causes contractions to pass also in the opposite direction. Nevertheless it was found that the latter only occurs when the irritant substance is introduced into the bowel in, so to speak, an unphysiological way. A solution of sulphate of copper was injected into the stomach, and quickly passed into the bowel, but, entering it thus, it caused only descending peristaltic contractions. Hence we must assume that, so to speak, performed arrangements exist, of an anatomical or physiological nature, which determine the direction of the movement.

How does faecal vomiting occur in cases of obstruction of the bowels? It will be remembered that many authorities, from the time of Van Swieten, have asserted that it does not necessarily occur by antiperistaltic contractions. Van Swieten maintained that it was by the action of the diaphragm and abdominal muscles, and Brinton urged with great ability that its mechanism must

be a reflex current in the centre of the distended intestine, opposed in its direction to that of the peristaltic action. Van Braam, Houckgeest and Lichtenstern have experimented on the subject, and were unable to discern any ascending contractions. Nothnagel has made a large number of experiments on this subject. Ligature of the small intestine caused in some cases very little effect. The intestine above gradually became filled without any marked contractions, and the portion below gradually became emptied. In other cases, however, a series of vigorous contractions passed down from the stomach, and distended the part immediately above the ligature, ceasing in the distended portion, and as this extended upwards higher, the section in which the peristaltic contractions occurred became smaller and smaller, until it was reduced to a narrow segment near the pylorus. After the distension had existed for half an hour, local contractions could no longer be excited by mechanical stimulation; the intestine was evidently paralyzed. In these cases there was no antiperistaltic action. In others, however, the descending contractions on reaching the ligature seemed to return up the bowel for a very short distance, and were even augmented in force just above the ligature, so that the intestine here was emptier than it was higher up. There was no regular antiperistaltic action, and after a short time these "rebounding contractions" ceased, and the distension and paralysis went on as just described. Sometimes, however, the peristaltic action quickly ceased, but the distended bowel seemed to undergo a slow imperceptible contraction, which caused its contents to pass upwards, because the ligature prevented them from passing downwards. In a series of experiments in which the intestine was ligatured through a small opening in the abdominal wall, and was returned into the cavity for some hours before the abdomen was opened, the events were found to be essentially the same. Various injections were also made into the intestine above the ligature. When indifferent liquids were injected, these were moved upwards, sometimes as much as thirty centimetres, although only by the descending peristalsis and the rebounding contractions already described as occurring just above the ligature. Injections of a concentrated saline solution, however, produced distinct ascending antiperistaltic waves, precisely similar to those produced in the unligatured bowel by the same injection, and by them the liquid was quickly moved upwards.

The paralyzing effect of the distension of the bowel above the ligature, which quickly annihilates its movements, throws an instructive light on the well-known injurious effect of purgatives in cases of intestinal obstruction. As they increase the peristaltic contractions, they carry the contents of the intestine more rapidly to the neighborhood of the obstruction, and so more quickly bring about the paralysis which follows distension.

The results of these experiments are certainly opposed to the idea that fæcal vomiting is the effect of any regular antiperistaltic contractions. These were only observed as the effect of the presence of irritant substances in the bowel, and the only condition in man to which this observation can fairly be applied is that in which irritating aperients, such as croton oil or colocynth, have been given. The simple diffusion of liquid contents causes their slow extension upwards, and a still greater effect is produced by the rebounding contractions, but the influence of both these was too slight to allow them to be regarded as the cause of fæcal vomiting. The conclusion of Nothnagel therefore is that this symptom results indirectly by the mechanism which Van Swieten rightly assumed. To some very instructive observations of Nothnagel on the movements of the intestines in other morbid states, we must return on another occasion.

THE GROWTH OF THE BODY.

THE course of the physical development of the human body has often been the subject of investigation, and most of the facts relating to it have been so carefully ascertained that it might seem that there is scarcely room for fresh researches on the subject. The facts of growth have been, however, once more verified, and, we must add, our knowledge of them has been extended by Dr. Thoma, who has described, in a volume of nearly three hundred pages, the observations he has made, which relate to the development not only of the body as a whole, but also of some of its constituent organs and tissue-elements, and thus constitute a very complete account of the subject. The comparison of his own measurements, and those of others, shows that to the usual excess of the body-length and body-weight of males over females, there is an exception between the twelfth and fifteenth year of life. At this period the development of the female equals, or even exceeds, that of the male, an indication of the earlier attainment of puberty in the female sex. Normal growth is not uniform, but presents an increased or lessened activity at different periods of development. The most rapid growth is observed in the last months of foetal life; after birth it gradually becomes slower, until some time between the sixth and ninth year. An acceleration then commences, which becomes most rapid between the thirteenth and sixteenth year, and after this epoch a progressive retardation is observed. The full height is attained at latest by the thirtieth year, but the average weight continues to increase. In later life both lessen. The variations from the average are greatest at the period of most rapid growth, and least when this is slowest. All the phenomena occur earlier in females than in males.

Of the internal organs, chief attention was paid to the heart and the kidneys. The average weight

of the heart undergoes the most rapid increase immediately after birth; its rate of growth gradually diminishes, but at puberty it presents a transient acceleration. After forty-five a slight increase in weight occurs, and no doubt, as commonly believed, this increase is the result of degenerative changes in the arterial system. Apart from these special influences the curve presented by the rate of growth has nearly the same shape as that which indicates the body growth. Like this, also, the chief deviations from the average are met with at the period of most rapid growth, immediately after birth. Thoma has given certain rules for comparing the weight of the heart and body, by which he believes that the existence of hypertrophy can be recognized with certainty even when it is too slight to be detected by ordinary methods of estimation. The rate of growth of the kidneys is nearly the same as that of the heart and the whole body; and the relation borne by the weight of the heart and of the kidneys to that of the whole body is nearly the same throughout life. At all periods of life the weight of the left kidney is greater than that of the right.

Measurements of the larger bloodvessels showed, amongst other facts, that the post-foetal growth is least in the common carotid artery, and greatest in the renal and femoral arteries, while the rate of growth of the subclavian is between these, and nearly corresponds with the aorta and pulmonary artery. These differences correspond with those which exist in the growth of the parts of the body to which the vessels belong. Up to the thirtieth year of life the pulmonary artery is, on the average, a little wider than the commencement of the ascending aorta. From facts which he has ascertained Thoma has formulated many very interesting mathematical conclusions.

Obituary.

SIR THOMAS WATSON, BART.

To the entire profession and to a very large portion of the public, from the Sovereign downwards, the death of this eminent physician, which occurred on December 11th, will be a source of deep sorrow. We purpose now to give a sketch of his very distinguished career.

Thomas Watson was born at Kentisbeare, in Devonshire, on the 7th March, 1792. He was educated at the Grammar School at Bury St. Edmunds, of which Dr. Malken was head master, where he was a contemporary of the late Bishop Bromfield, with whom he always retained an intimate friendship. On leaving Bury school he was entered as a pensioner in St. John's College, Cambridge, of which college his uncle, Mr. Catton, was then a resident Fellow. He graduated B.A. in 1815, being placed tenth in the list of wranglers, was elected a Fellow of his college in the following year, and became M.A. in 1818. According to the rules then in force at St. John's College, no Fellow could retain his Fellowship for more than a short time without being ordained. From this rule, however, two Fellows were exempted, one of whom

was to study medicine. A vacancy having occurred he availed himself of it, and retained his Fellowship until he married in 1825. During his residence at Cambridge as Fellow of his college, a period of eight years, he took private pupils, many of whom (including, amongst others, the late Lord Auckland, Bishop of Bath and Wells, and Lord John Thynne) continued their friendship with him in after life. He served the office of junior proctor in the University of Cambridge in 1823 and 1824.

In 1820 and 1821 he attended the medical classes in Edinburgh, and in a letter to his sister dated from Edinburgh he speaks of his intention to return thence in a sloop as being more economical and allowing the carriage of an unlimited amount of luggage. During his residence at Cambridge he made the acquaintance of his future wife, a daughter of Edward Jones, Esq., of Brackley, in Northamptonshire, who, as a favorite niece of the Rev. Dr. William Turner, then Dean of Norwich and master of Pembroke College, was a frequent visitor to Pembroke Lodge. They were married in 1825 in St. Luke's Chapel in Norwich Cathedral, and in the same year he took his M.D. degree. In the following year Dr. Watson was elected a Fellow of the College of Physicians, and in May, 1827, Physician to the Middlesex Hospital, an office which he continued to hold until November, 1843. For some years after he settled in London practice came very slowly, patients and fees were few, and he was not free from pecuniary cares and anxieties. In September, 1830, he had the great grief of losing his wife, who died suddenly three days after the birth of their second child. In a letter written to his sister a few days after this terrible blow occurs this characteristic sentence: "My business henceforward in this life must be to endeavor to train up the children as nearly as I can as she would have trained them, and so to live as to acquire, through God's blessing, a hope that we may all hereafter meet their poor mother in happiness."

At the opening of the medical school of King's College in the autumn of 1831 Dr. Watson was appointed Professor of Forensic Medicine, and what we believe to be his first contribution to medical literature appeared in the *Medical Gazette*, vol. ix., 1831, entitled, "Remarks on the Dissection of Bishop, and the Phenomena attending Death by Strangulation." Bishop had been hanged for the murder of an Italian organ boy, whose body he brought to the dissecting-room of King's College for sale. The late Professor Partridge had his suspicions excited, and gave the man Bishop into custody. He was tried and condemned, and after his execution his body was sent to King's College for dissection. After this Dr. Watson was a frequent contributor to the *Medical Gazette*. The same ninth volume contains clinical lectures "On Pulmonary Hæmorrhage and on Epilepsy." In the tenth volume there are the Lumleian lectures on "Hæmorrhage from the Stomach, Intestines, and Urinary Organs." In the thirteenth volume there is an admirable introductory lecture, delivered at the opening of the medical session at King's College. In the fifteenth volume appears a paper "On the Efficacy of the Vapor Bath in Cases of Diabetes." The sixteenth volume contains two lectures "On Rheumatism of the Heart," and a paper "On the Connection of Hypertrophy of the Heart with Cerebral and Pulmonary Hæmorrhage." In July, 1832, Dr. Watson accompanied Sir Walter Scott from London to Edinburgh on his last sad journey from Italy to Abbotsford. In "Lockhart's Life of Scott" it is stated that Dr. Watson went the whole way to Abbotsford with Sir Walter; but in a copy of the work which he gave his son

Dr. Watson has written the following foot note: "This is a mistake of Mr. Lockhart's. I did not accompany Sir Walter to Abbotsford, but returned from Edinburgh to London."

In 1836, Dr. Watson was appointed Professor of Medicine at King's College, and he continued to hold this office until the spring of 1840, when, at the opening of the newly-founded King's College Hospital, he had to resign either his office of physician to the Middlesex Hospital or his chair at King's College, and he preferred to retain the former office. The resignation of his professorship, which was felt as a calamity by King's College, was attended with this great benefit to the entire profession and the public, that it led to the publication of his admirable lectures on the "Principles and Practice of Physic." The lectures were first published week by week in the *Medical Gazette*. The first lecture appeared on Sept. 25th, 1840 (vol. xxvii.); and the last of the series on Sept. 23rd, 1842 (vol. xxx). In the following year, 1843, they were collected and published in two volumes by Messrs. J. W. Parker & Son, West Strand; a second edition was called for in 1845; and a third in 1848. Two editions have since been published; one in 1857, and, lastly, the fifth in 1871.

The publication of these lectures, admirable as they were universally acknowledged to be, not less for the soundness of their teaching than for their lucid, elegant, and scholarly style, greatly increased the reputation of their author, acquired for him the well-merited title of the Cicero of English medicine, and led at once to a large extension of his practice. The well-known volumes had, for a number of years, probably a larger sale than any other similar work that has ever been published, and we have pleasure in recording here an anecdote illustrative of his publishers' liberality, which was related to us by Sir Thomas Watson. Mr. Parker one day called on him and said that the sale of his lectures, and the profit resulting therefrom, had so far exceeded his (the publisher's) anticipations, that he did not feel justified in sharing the profits equally with the author, according to the terms of their original agreement; he therefore proposed that the author should receive two-thirds of the profits, while the publisher retained one-third. And as a practical illustration of his generous intentions, he handed the author a cheque for twelve hundred pounds. This surely is an example of liberality not unworthy of imitation.

At the College of Physicians Dr. Watson held numerous offices before he was elected President. In 1827 he was Gulstonian Lecturer; in 1830-31 Lumleian Lecturer; in the years 1833, 1834, and 1835 he gave the College lectures on *Materia Medica*; he was Censor in 1828, 1837, and 1838; on the Council at various times between 1833 and 1868. From 1858 to 1860 he was the College representative on the Medical Council. In 1862 he was elected President, and he held that office for five successive years. The College would have gladly elected him for a sixth period of office; but he declined on the plea of advancing years, and at the annual meeting for the election of President, after referring in graceful terms to the Fellows who had died during the previous year, he bade the College, as their President, farewell in the following eloquent and characteristic words:—"It only remains that I should attempt to do that which I feel to be well-nigh impossible—to embody in any form of words that I can devise the deep and inextinguishable sense of gratitude with which my mind is full for that kindness and trust which have placed me, year by year, on five successive occasions, at the head of the College of Physicians; in other words, at the head of the medical pro-

fession in this great country. According to my estimation, already more than once expressed, there is no nobler position in medicine, whether I look before me and around me to the body of men from whom it comes, or backwards to the splendid list of names of those who have preceded me in the presidential chair—Linacre, Caius, Glisson, Sir William Browne, Pitcairn, Sir George Baker; these, to go no later, are but a few of the eminent men and sound scholars with whom it may well be deemed a proud distinction to have one's name in any way associated. But, besides this great and repeated honor—the greater because so repeated—I have much else to thank you for. I have to acknowledge your indulgence towards the many shortcomings of which I am but too conscious. I have to express my thanks for your constant support and counsel in all difficulties, for your unvarying courtesy and deference, for the friendships which my official intercourse with you has formed or strengthened, and most especially for that recent signal and touching evidence of your approbation and esteem shown by your wish to possess within your walls some pictorial remembrance of my unworthy person. Of this high and generous compliment I can never, while life and reason remain to me, be otherwise than most gratefully, and I hope pardonably, proud. Further, I have to rejoice that the happy *lustrum* during which I have presided over your affairs has been harmonious and peaceful—disturbed by no unseemly quarrels or serious differences among us—stained by no scandal arising within our proper body, and productive, through your exertions and self-sacrifices, of something at least of benefit to the common weal. If I find anything to regret it is that I have not taken larger advantage of the opportunity which you have confided to me of promoting the interests of the College, and of our useful and noble profession.

Still, I must cherish the hope that the College has suffered no abatement of its ancient dignity and renown through my occupation of the office, which I now respectfully render back into your hands. And so, without encroaching further upon your time and in redemption of the pledge which I gave you last year, I bid you, as your President, one and all, a cordial, affectionate, and final farewell.

The "pictorial remembrance" to which he refers is an admirable portrait by his old friend, George Richmond, which was subscribed for by a large number of the Fellows, and which is now amongst the most cherished treasures of the college. A replica is in possession of Sir Thomas Watson's family, and it has been successfully engraved by Samuel Cousins.

Dr. Watson was appointed Physician Extraordinary to the Queen in 1859, and in 1870 one of the Physicians in Ordinary. On the 9th December, 1861, he was summoned to attend the Prince Consort at Windsor in consultation with Sir James Clark, Sir Henry Holland, and Sir (then Dr.) William Jenner, and his attendance continued until the lamented death of the Prince on December 14th. In 1866 Dr. Watson was created a baronet, the honor having been offered to him, as he was informed by the then Prime Minister, Lord John Russell, by the express desire of Her Majesty. Amongst other distinctions which were conferred upon the great physician, he was elected an Honorary Fellow of his old college, St. John's, at the same time with the late Sir John Herschell. He was Hon. D.C.L. Oxford, 1862; Hon. LL.D. Cambridge, 1864; and Hon. Fellow of King's and Queen's College of Physicians, Ireland.

In 1859, he was elected a Fellow of the Royal

Society. For many years he was a most influential member of the Council of King's College, London. During the session 1857-8, Sir Thomas Watson was President of the Pathological Society. In 1868, he became the first President of the Clinical Society; and in his inaugural address he urged upon the Society, with his customary good sense and grace of style, the supreme importance of an endeavor to obtain "more exactness of knowledge and therefore more direct and intelligent purpose, and more successful aim in what is really the aim and object of all our labors—the application of remedies for the cure and relief of disease."

During the last ten or twelve years of his life he had retired from the active practice of his profession, but continued to take great interest in all that concerned it.

Notwithstanding his advanced age, he enjoyed his usual good health, spending great part of the last summer and autumn with his daughter and his son's family, partly at the seaside and partly at his son's house, Reigate Lodge, Surrey. On Sunday, Oct. 22nd, he had attended the morning service, as usual, at the parish church. On attempting to rise from the table, after lunch, he made a sudden inclination towards the left side, and would have fallen if he had not been supported by his son, who was standing by him. He afterwards took a short walk in the garden, but the left leg was found to be weakened, and he walked with great difficulty. He was seen at once by his neighbor, Dr. Walters, and on the following Wednesday he was visited by his old pupil and friend, Dr. George Johnson, to whom he calmly said, "This is the beginning of the end." There was then some paralysis of the left leg and of the left side of the foot and tongue, but there was no appreciable weakening of the arm. The mental faculties and the power of speech were quite unimpaired. Drs. Johnson and Walters were of opinion that there was probably obstruction by thrombosis in some of the smaller cerebral arteries.

On the following Thursday, Oct. 26th, after some exertion in walking across the room (up to this date he had been dressed daily and had gone downstairs), he was suddenly seized with difficulty of breathing, his face became blue, and he believed himself to be dying. There appeared to have been some sudden failure of the heart's action; but in the course of an hour or two the distress passed off. He was then carried to his bed; and from that day he did not leave his room, and rarely could even be moved from his bed. It is neither necessary nor desirable to dwell on the details of the subsequent seven weeks. The condition was one of increasing weakness and often of most distressing restlessness. Then there came irritation of the bladder with some retention, for which Dr. Walters was prepared to render the needful aid; but the restless sufferer, with a firm conviction that he had stone in the bladder, insisted on having Mr. Lister telegraphed for; and it was not until Mr. Lister had been sent for and had come a second time that he would allow Dr. Walters to give him the relief which henceforth was required two or three times daily.

During the last few weeks, a little milk with a small quantity of brandy was all the nourishment that could be taken. Weakness and emaciation, with a falling temperature, steadily increased. He retained his consciousness until within the last two days of his life, although his power of speech was latterly much impaired. It was believed that he understood and was gratified by a kind message of inquiry and sympathy from her Majesty the Queen. He was often soothed by the reading of a prayer or a hymn.

At length he sank into a slumber, and so on Dec. 11th, near midnight came the final rest for which he had longed and prayed. To quote his own words with reference to his old and beloved friend, Dr. P. M. Latham, "Ripe in years as he was, and ready in spirit for the solemn change, his death must long be the subject of tender and sacred regret among the nearest and dearest of his surviving family and friends; nor will his memory soon cease to be reverently cherished throughout a much wider circle."

Throughout the trying seven weeks of weakness and of suffering Sir Thomas was most assiduously attended by his kind friend and neighbor, Dr. Walters, and occasionally by Dr. Holman. He was also seen from time to time by his neighbor, Dr. Greenhow, who was always ready to render assistance when needed, and he was frequently visited by Dr. George Johnson. We have already mentioned that Mr. Lister twice obeyed the distinguished sufferer's summons. It need scarcely be said that all felt it a privilege to minister to the relief of one so universally revered and beloved.

Reviews and Notices of Books.

Report on the Scientific Results of the Voyage of H.M.S. "Challenger" in 1873-76, under the Command of Captain George Nares and Captain Frank Thomson. Prepared under the superintendence of Sir C. WYVILLE THOMSON, F.R.S. Vol. III: Zoology. London: Longmans & Co.; John Murray; Macmillan.

THIS volume contains a report on the Echinoidea, dredged in the course of the voyage, by Alexander Agassiz; and a report on the Pycnogonida, by Dr. P. P. C. Hook, assistant at the Zoological Laboratory of Leyden University.

Agassiz states that a careful comparative study of the new species collected by the *Challenger* and by the *Blake* seems to make a short revision of some of the principal lines of the recent and fossil Echinids desirable, as, from our present knowledge of the affinity of the Echinoidea, several groups formerly considered somewhat aberrant can now be shown to be closely connected. The consideration of this group could have passed into no better hands than those of Alexander Agassiz, for he possesses an extensive acquaintance with both the recent and fossil specimens, and has himself examined all but a few of the deep-sea species, whilst he has had the further advantage of describing the first important collection of deep-sea echinids made by Count Pourtales. He holds that the artificial classification of the Echinoidea at present accepted is unsatisfactory, because based upon characters of such uncertain value as the presence or absence of teeth and of actinal cuts. He founds his classification of the echinids on that of Loven, which he regards as by far the most ingenious that has yet been proposed, and who has suggested a most admirable notation to denote the several ambulacral and interambulacral areas, which simplifies to a remarkable degree the comparison of the various types. The number of fossil species is about 2,000, whilst there are not more than 300 recent, and about one-third of the whole number of known species have been discovered since the days of deep-sea dredging; but the difficulty of tracing the genealogy of these is almost insuperable, for, as he shows, the number of variable terms are at least twenty—viz., the apical system, the actinal system, the genital, ocular, anal,

and coronal plates, the ambulacral and interambulacral areas, the poriferous zone, the primary, secondary, and miliary tubercles and their corresponding spines, the modifications of the poriferous zone near the apical and actinal systems and on the test; the fascioles, jaws, alimentary canal, the position of the apical system, of the anal system, of the actinostome, and the modifications of the same; and when we consider that these may be combined in all possible ways, it is hazardous, to say the least, to attempt anything beyond the broadest indications of the outlines of the relationship.

The study of the Echinids dredged by the *Challenger* has shown very plainly the antique character of many of the deep water species, and their resemblance to Cretaceous genera, and Agassiz points out many noteworthy relationships. He remarks that in comparing the Tertiary fossil Echinids of the European beds with the species now living in the West Indies, it is impossible to avoid being struck with the similarity existing between them. Thus the species of *Cidaris*, *Clypeaster*, and others, which are found in the Tertiary beds of Malta, are no longer found in the Mediterranean, having undoubtedly disappeared from that sea as soon as it became closed, and the temperature of the water became raised above that of the ocean; while, on the contrary, where the oceanic conditions have not undergone any great change, we find a remarkable identity in the genera of the Tertiaries and of the surrounding deep sea, as can be easily seen by comparing the Tertiary West Indian types of *Echinolampas*, *Agassizia*, *Brissopsis*, and others, with the species of the same genera now found in the deep waters of the Caribbean Sea and Gulf of Mexico.

The number of deep sea species discovered by the *Challenger* appears to have been forty-nine, whilst forty-one were discovered by the *Blake*, *Porcupine*, and *Josephine*. The plates are sixty-four in number, many of them representing several forms.

We must refer to the original for the descriptions and beautifully executed lithographs of the numerous new species collected by the *Challenger* and the *Blake*. Many interesting facts are related in the account of each genus and species. Thus, under "*Goniocidaris*," he quotes Thomson's "*Voyage of the Challenger*," to the effect that the eggs, after escaping from the ovary, are passed along on the surface of the test towards the mouth, and the smaller spines articulated to the tubercles round the peristome are bent inwards over the mouth, so as to form a kind of open tent, in which the young are developed directly from the egg, without undergoing any metamorphosis until they have attained a diameter of about 2.5 mm. Even before they have attained this size the more mature or more active of a brood may be seen straying away beyond the limits of the nursery, and creeping with the aid of their first few pairs of tentacular feet out upon the long spines of their mother; after a short ramble they return to the marsupium.

In regard to the Pycnogonidae the results of the *Challenger* dredgings are most satisfactory, for it appears that of the forty-one species obtained during the voyage of the *Challenger* and the cruise of the *Knight Errant*, thirty-three are new to science, and of the nine genera represented three are new. The pycnogonids are long-limbed aquatic animals, distantly resembling a spider or a "daddy long-legs," or a spider crab. They breathe by the general surface of the body, which body consists of a cephalo-thoracic segment, three thoracic segments, and rudimentary abdominal segment. They have a proboscis and three pairs of cephalic appendages, of which the first represents antennae, whilst the two others are post-oral. The thoracic par of

the cephalo-thoracic segment and the three thoracic segments are each furnished with a pair of long eight-jointed legs, into which the alimentary canal sends off long cæca. The nervous system shows a supra-oesophageal and five thoracic ganglia. The eyes are feebly developed in the deep water species, but rather highly developed in the shallow water species. The sexes are separate. The paper is illustrated by twenty plates, seven of which are devoted to the elucidation of the internal structure of this curious group of animals.

The Physicians' and Surgeons' Visiting List, Diary, Almanack, and Book of Engagements for 1883. Thirty-seventh year. London: John Smith & Co.

THIS season of the year reminds us that we must renew our visiting lists, than which nothing contributes more to the easy and methodical discharge of medical duty. Of these none holds its ground better than Smith's, which this year, amongst its new features, has a useful list of so-called "American Eclectic Remedies" and other doses, which is not always to be found in available works of *materia medica*. The doses of remedies do not always correspond with those given in the *Pharmacopœia*. Sometimes a larger dose is recommended than that of the *Pharmacopœia*, as in the case of *ext. nuc. vomic.*; sometimes a smaller, as in the case of *tinct. conii*. We think it would be better to give the *Pharmacopœial* doses. The book is full of useful tables, including one of corresponding degrees on different thermometric scales, one of days of incubation of eruptive fevers, etc., and is altogether too well known to need further commendation.

Études de Physiologie Sociale: La Prostitution. Par Yves Guyot. Paris: G. Charpentier. 1882.—This laborious work has been written with the well-conceived purpose of proving that the various legislative measures in force with regard to prostitution, in their relations to the preservation of the public health and morals, have not only altogether failed in these respects, but have exaggerated the evils they were intended to suppress. We will see upon what grounds, and by what arguments, the author supports these positions, and to what extent he has succeeded in establishing them. He commences by asking, "What is prostitution?" and, accepting the definition of Littré—"An abandonment to unchastity"—very properly remarks that the term is applicable to either sex. But when he pushes his premises farther, and claims for the word "prostitute" a similar latitude, he contends for a point of no practical value, inasmuch as it is universally understood to mean an abandoned woman. He then gives a graphic account of the cruelty and atrocities exercised against this unfortunate class of females, at various times and in divers countries, from the time of Solon and Charlemagne to more recent periods. He is very eloquent on the effects of the unequal laws that govern the relations between the sexes; but though he moves us to pity that the insanitation and infamy of the one should be punished and not of the other, yet he has failed to suggest any remedy for them. It appears, from his numerous records on the subject, that until the nineteenth century the legal regulations with regard to prostitution had for their sole object the preservation of the public morals, and that it was not till the period mentioned that the question of sanitation was conjoined with it. With a minuteness of detail often revolting in its gross indecency, and which no

English author would have dared to have published he explains the *modus operandi* of the "French system," as administered by "the police of morals," together with the medical staff connected therewith. The primary object of this system, it would seem, is to concentrate prostitution into certain licensed houses, "*des maisons de tolérance*," and confine it, as far as possible, to certain districts; and in the desire to attain this the author says that its administrators are often "brutally harsh, venal, and unjust." The result has been a moral degradation of both the women and their clients of so frightful a nature that it is appalling to contemplate it; and we may well felicitate ourselves that a system that encourages or permits the herding together of a number of women in one house, under the tutelage of a vile wretch, "*la maîtresse de la maison*," who often becomes affluent through her abominable traffic, has not, and never can have, any legalized existence in this country. M. Guyot makes an assertion to the contrary. He says: "Since the passing of the Contagious Diseases Act licensed houses have greatly increased at Aldershot, and the police have fostered this movement." We are in a position, from inquiries recently instituted on these points, to give an emphatic denial to this statement. The authorities say "such houses have greatly decreased, as has also the number of prostitutes, and very young girls are now seldom seen in the streets." Nothing can be more explicit than this, and nothing more satisfactory; for it would be impossible to devise a more certain means of undermining the health and morals of the rising generation than by legally countenancing an institution such as has been so realistically described by the author. It is, however, in its relations to the public health that this system more immediately concerns us, because our own Contagious Diseases Act, intended for an analogous purpose, is largely modelled on that portion of it that applies to sanitation. Here the author has entirely failed to make out his case. How does he attempt to establish it? In the first place, from the fact of there being relatively more venereal diseases amongst women in licensed houses, who are medically visited once a week, than amongst *les filles isolées*, women living alone in furnished rooms, who are obliged, or rather expected, to go to the dispensary once a fortnight, he concludes that medical intervention in this respect increases these diseases amongst them. He himself has unconsciously furnished proof of the fallacy of this deduction, for he states "that while the former cannot exercise any choice in the selection of their clients, and are obliged to receive a much greater number, six to twenty-five daily, the latter can exercise that selection and are able to please themselves as to the number of their receptions." Moreover, he says, "the first are always amenable to examination, while the others are made to submit with much more difficulty, and often go away when diseased to avoid being sent to hospital." Comment on this is superfluous, and statistics handled in this way are worse than useless. Another argument he advances in support of this position is that "it is almost impossible to discover a primary infecting chancre or to decide the nature of vaginal discharges in a woman." This assertion is contrary to experience, for though, no doubt, it may be difficult in some instances to detect the one or differentiate between the several kinds of the other, yet in the majority of cases it will not be so. Besides, irrespective of this, are not syphilitic mucous patches infective? And is there anyone so obtuse as to deny that when the subject of them is sent to hospital for treatment a fruitful source of infection has been withdrawn from circulation? It is idle to attempt to refute

such statements as these, and if those who are agitating for the repeal of the Acts in question have no stronger testimony to bring forward than this their case is desperate indeed. The French system is utterly demoralizing, but the legislation exercised in this country has an opposite effect, for it has been proved by numerous letters in *THE LANCET* and elsewhere, and by other testimony, that many young women, more impressionable than those more hardened in sin, have been rescued from their evil courses by the interposition of these Acts, and this is a sufficient answer to a favorite theory of the repealers that "the duration of time during which prostitutes exercise their calling has been greatly prolonged by the influences they have exerted." If they are enforced efficiently, and the medical examinations are conducted with proper skill and care, it is absurd to suppose that the diseases for the prevention of which they were passed are not correspondingly ameliorated. M. Guyot's elaborate ventilation of this subject will undoubtedly do good, and we strongly recommend all interested in it to read the book for themselves.

On Duty under a Tropical Sun: being some Practical Suggestions for the Maintenance of Health and Bodily Comfort, and the Treatment of Simple Diseases, with remarks on Clothing and Equipment for the Guidance of Travellers in Tropical Countries. By Major S. LEIGH HUNT and A. S. KENNY, M.R.C.S.E. pp. 138. London: Allen & Co. 1882.—The object of this work is to assist persons visiting tropical climates to counteract and palliate many of the petty annoyances and personal discomforts to which, from lack of experience, they may be exposed. The remarks on diet and the suggestions on clothing and equipment seem well calculated to be useful to the class for whom they are intended, but we are afraid that the remarks upon the diseases of tropical climates and the directions for their treatment will rather have a tendency "to foster a false sense of security by leading anyone to think it is possible for him to dispense with proper medical assistance when these evils befall him." This is far from the intention of the authors, who endeavor to impress upon their readers the "imperative duty" of availing themselves of the skill and experience of medical men acquainted with the diseases of the country; but we entertain doubts as to the practical results of the attempt in the direction of "domestic medicine."

Metropolitan Sewage, and what to do with it. By EDWARD MONSON, A.M.I.C.E. Part I. London: Prentice & Monson.—Mr. Monson's small work appears opportunely at a period when so much attention, both public and private, is being given to the condition of the Thames as the result of the metropolitan outfalls for sewage. The whole history of the London sewerage system, and of the formation of the Metropolitan Board of Works, is entered into, and much of the action of the board is sharply criticised, both on account of the plan on which some part of the sewerage works have been designed, and because the scheme has never been carried out in its entirety. Especially does the author complain that flooding of houses, insufficiency of sewer provision, needless expense, and other difficulties have resulted from the initial error of not separating streams with much of the rainfall and the storm-water from the sewage proper. The sewers are in consequence of enormous size; they are, notwithstanding their huge capacity, totally inadequate to carry off storm-water, and the sewage which, under a separate system, could have been concentrated at a point

where it might easily have been either chemically treated or utilized, is so diluted and in such quantity that the question of its proper disposal has never been faced. As a result, the effect of discharging the metropolitan sewage into the Thames has been to cause a nuisance of imperial magnitude and concern; shoals of sewage mud are found in the river; and very general complaint emanates from the Thames Conservancy, the Port Authority and the riverside population. Even now Mr. Monson maintains that there would be true economy in reconsidering the system as a whole, and he specially advocates that the sewage should be treated by the lime process before the effluent is passed into the river. With regard to the sewage sludge which would result from this process, Mr. Monson points out how much it partakes of the character of the washed clay and chalk used in the manufacture of stock bricks; and he shows, as the result of actual experiment, not only that in this direction will in all probability be found the remedy for that accumulation of apparently useless sludge which has so often been associated with the lime process of dealing with sewage, but that the utilization of the sewage sludge in the manner he proposes will open out a great future for the manufacture of a brick which will be much sought after in building operations.

What to do in Accidents and Sudden Illness, etc. By PHILIP FOSTER, M.D. pp. 76. Leeds: Spark.—This is one of a class of books which, if not called into existence, has, at least, been greatly developed by the formation of ambulance classes. The work now before us is not, however, confined to instruction in what should be done on the occurrence of an accident or the infliction of an injury, but covers a much more extensive field. It discusses the conditions necessary for the preservation of health and the prevention of disease among the people generally; the duty of sick nursing; "the symptoms and treatment of certain ailments for which medical advice is frequently not sought, and of some others in which serious consequences might ensue before it could be obtained," including cases of poisoning; and concludes with a few remarks on the rearing of children. The work seems to have been carefully drawn up, and on the whole to be judicious and well calculated to answer the purpose intended. We think, however, it might have been abridged without detriment by the omission of the introductory chapter on the structure and functions of the body; and we must protest against the author's opinion that "the duties pertaining to the office of the nurse do not call for special knowledge or training." There may possibly be good nursing without these, but it is the rare exception to the rule. We hold that no greater improvement has taken place in the treatment of the sick than the introduction of a thorough practical training of the nurse.

Diseases of the Ear. By GEORGE P. FIELD, M.R.C.S., Aural Surgeon to St. Mary's Hospital, and Lecturer on Aural Surgery in the Medical School. Illustrated with colored plates and woodcuts. London: Henry Remshaw. 1882.—We have noticed the previous editions of this book, and are not now surprised to receive a third edition. The class of diseases of which it treats are of great importance, and yet unfortunately are seldom the subject of much attention in medical education, either on the part of the student or his teachers. Mr. Field does his best, and does well, to make up for this defect. His book will be found very useful both by students and practitioners. This edition contains many new illustrations and several additional chapters.

Medical Annotations.

"Ne quid nimis."

A NEW VEGETABLE STYPTIC.

A RECENT number of the *Neue Freie Presse* states that during the French expedition to Mexico a plant was discovered, called by the natives by a name which may be rendered as "Fowlwort" (*Tradescantia erecta*, Jacq.), which has the property, when chewed or crushed, of stopping any hæmorrhage. A specimen planted in 1867 by the discoverer, in his garden at Versailles, has not only flourished, but flowered and fruited, without having its peculiar properties as yet appreciably diminished. Although no exotic, or remarkable for particular beauty of bloom, it, nevertheless, deserves a wider extension on account of its valuable properties, especially as its acclimatization may be regarded as having been fully established. Its action exceeds that of all styptics as yet known, as, for example, perchloride of iron, and it can, moreover, be very cheaply procured.

THE DANGERS ATTENDING SHAMPOOING.

RECENT and unsatisfactory experience in one or two West-End hair-cutting saloons leads us to inquire whether sufficient care has been bestowed on the sanitary management of the shampooing contrivances. Those persons who avail themselves of the very refreshing pleasures of a "shampoo" must, however, have noticed that they are compelled to bend over, and bring their faces in close proximity with, the hole in the centre of the huge basin used for this purpose. If they watch the soapuds that form around this hole before any large volume of water is allowed to flow, they may perceive the air coming up the pipe; for it inflates the soap and forms a large bubble that bursts close under them. Whatever may be within, it is too near to avoid breathing its contents. Nor does the absence of any suspicious odor inspire a sense of security; for it is very evident that even a strong whiff of sewer gas would be lost in the scent that perfumes the soap and surrounding atmosphere. If therefore the pipes attached to the basins communicate direct with the house-drains and the sewer, there is surely some danger that the atmosphere breathed within a couple of inches of the aperture may carry, disguised under the fragrance of the rose or jassamin, the virus of disease. In one of the most celebrated West-End houses we noted that the pipes from the shampooing basins all led on to the roof of an outhouse, and there the soapuds and water travelled some three or four yards in the open air before reaching the water-spout that conveyed them to the sewer. A back current could therefore only bring in air from the roof—that is, air as pure as any to be had in London. But in another house nearly as celebrated the pipe from under the basins ran direct to the drains. There was no S-trap visible, and apparently no intercepting ventilation. The basins had, in fact, all the appearance of so many sewer mouths, ventilating the sewer-gas into the faces of the customers as they leaned over the aperture. Even a syphon in such cases is not, we maintain, a sufficient protection; the constant flow of water, the difference of temperature between the hot and cold water, and the varying degrees of density of the water through the presence in small or larger quantities of soap, oil, etc.—all these circumstances must so affect the pressure and tension of the air within the pipes as to produce suction, up

currents, and syphonage. Consequently it is indispensable that all the pipes conveying the waste from hairdressers' saloons should empty in the open air over a gully-trap or an interceptor, and should not have any direct connection with either the house drains or the public sewer.

SUMMER DIARRHŒA IN 1882.

JUDGED by the figures published from time to time in the Registrar-Generals' weekly return for twenty-eight of the largest English towns, with an aggregate population of about eight million and a half of persons, it is evident that the fatality of diarrhœa during the past summer, although slightly higher than it was last year, was again considerably below the average. In London the annual death-rate from this disease showed a larger proportional decline than in the provincial towns, and did not exceed 1·5 per 1000, against 3·2 and 2·5 in the summers of 1880 and 1881. The rates in the large provincial towns showed the same, a similar variation which should throw light upon the true causation of this disease, but which has not yet led to its satisfactory explanation. During the thirteen weeks ending September 30th last the death rate attributed to diarrhœa did not exceed 0·9 in Halifax, 1·0 in Bristol and Derby, and 1·3 in Plymouth and Huddersfield, whereas the highest rates in the other provincial towns were 4·0 in Leeds, 5·7 in Leicester, 5·8 in Hull, and 6·0 in Preston. All these towns are old offenders in respect of infantile diarrhœa, and of infant mortality generally. It is also noticeable that while, as we have stated, the death-rate from diarrhœa last quarter in these large towns showed a general increase upon that in the corresponding period of 1881, the rate of increase varied in a marked manner; indeed, in several of the towns the rate showed a decline. All these facts point conclusively to controlling influences other than meteorological. It may be hoped that the Local Government inquiry on this subject, now being conducted by Dr. Ballard, will throw satisfactory light upon this much discussed but yet unsolved problem.

THE LATE PROFESSOR BALFOUR.

AN influential meeting was held on Oct. 21st, 1882, in the Lecture room of Comparative Anatomy at the New Museum, Cambridge, to consider the best mode of establishing in the University a memorial of the late Professor Balfour. The Vice-chancellor presided, and the meeting was attended by Professor Huxley, Messrs. H. Smith, Lankester, Foster, Paget, Humphry, Newton and others. Great regret at Professor Balfour's untimely close of a career so full of promise was expressed by every speaker. Professor Paget proposed the first resolution, that a memorial of Professor Balfour be established in the University of Cambridge which was seconded by Mr. H. Smith. In supporting this resolution Mr. Adam Sedgwick instanced as proof of the attractive address and teaching of Professor Balfour that his class which at first only consisted of ten or twelve students, had in the course of seven years increased to ninety. Professor Huxley then proposed that the memorial take the form of a fund to be called the Balfour Fund for the promotion of research in biology and especially animal morphology. Professor Newton proposed, and it was unanimously agreed upon, that the proceeds of the fund should be applied to establish a studentship, the holder of which shall devote himself to original research in biology, especially animal morphology, and further, that the fund should supply occasional grants of money for the furtherance of original research in the same subjects.

Professor Foster finally proposed that the studentship should be endowed with £200 per annum, and that it should not be given away by competitive examination. It was stated at the meeting that £3000 had been subscribed by the family of Mr. Balfour, and that £1000 which he had himself bequeathed to Professor Foster would be expended in promoting the objects aimed at in the memorial.

BLOOD AND OZONE.

It is usually asserted by physiologists that even traces of ozone, introduced into the blood, injure it by leading to the formation of methæmoglobin, and conversely ozone in contact with blood quickly undergoes destruction. The question has been re-investigated by Professor Binz, of Bonn, who has found that pure ozonized air has an action on human beings quite similar to that of nitrous oxide. Persons whose respiratory passages are so little irritable that they can take a full inhalation, experience a brief agreeable stimulation, and then become somnolent and actually fall asleep for a short time. This observation has led him to make further experiments on the tolerance of blood for ozone. He found that a stream of ozonized air might be passed through defibrinated blood for at least an hour without the occurrence of any change in its aspect, or microscopical or spectroscopical appearances. The only difference is that the alkal-escence diminishes more than in similar blood, through which simple pure air is passed. The ozone manifestly first combines with the dissolved organic elements of the blood, and only acts on the formed elements after prolonged action. A small quantity of blood subjected to a similar current of ozone first becomes bright red, then darker, and, at the end of an hour, it resembles reduced blood in aspect, but differs from this in not regaining its tint when shaken up with air. Its spectrum presents weak but unmistakable oxidation lines, which are not accompanied by methæmoglobin lines until the following day. Microscopically the blood-corpuscles were pale, and apparently spherical, and no fragments were visible. In another series of experiments the ozonized air was passed through fresh blood, to which a little saline solution had been added. At the end of ninety minutes the blood was uncoagulated, dark, but still showing oxygen lines, and the corpuscles had lost their depressions. A longer exposure rendered the blood very dark, and the next day the corpuscles had disappeared, and the methæmoglobin had considerably increased in quantity. A solution of pure oxyhæmoglobin resisted the action of the ozone much less than the blood, although it never presented alterations in less than ten minutes. Binz further ascertained that the decomposition of ozone by blood is not complete; considerable traces seem to remain in the blood in an unaltered state, and can be recognized by the usual tests.

OUR ORIGIN AS A SPECIES.

THE first number of *Longman's Magazine*, to whose prosperity we wish well, contains an article by Professor Owen with the above title, and which is a polemic upon a paper by Grant Allen in a late number of the *Fortnightly*. That author had rather strongly insisted on the evolution of man from some man-like animal developed from the anthropoid apes, and living about the mid-miocene period; a creature that was partly frugivorous, partly carnivorous—a tall and hairy creature, more or less erect, but with slouching gait, black-faced and whiskered, with prominent prognathous muzzle and large pointed canine teeth, those of each jaw fitting into an interspace in the opposite row:

the forehead low and retreating, with bony bosses underlying the shaggy eyebrows; his brain about halfway between that of the anthropoid apes and that of the Neanderthal skull. Then came the Pleistocene period, and with it the age of the cave-men, who presented some similarity to the existing Eskimo, but with lower foreheads, with high bosses like the Neanderthal skull, and big canine teeth, like the Naulette jaw. Professor Owen, in commenting upon these statements, observes that the human jaws of this supposed period which he has examined give no evidence of a canine tooth of a size indicative of one in the upper jaw necessitating such vacancy in the lower series of teeth, as the apes present. He refers to the skulls he himself obtained from the cavern at Bruniquel, and now in the Museum of Natural History, which show neither lower foreheads nor higher bosses than do the existing races of mankind, and he makes an observation which, coming from such an expert, is of great weight—that, so far as his experience has reached, there is no skull displaying the characters of a quadrumanous species, as that series descends from the gorilla and chimpanzee to the baboon, which exhibits differences, osteal or dental, on which specific and generic distinctions are founded, so great, so marked as are to be seen in the comparison of the highest ape with the lowest man. Clearly the missing link has not as yet been discovered, and many more undoubted specimens of river-drift and cave-men must be collated before any positive statements can be made.

PEAT DRESSINGS.

At the suggestion of Dr. Neuberg, Professor Es-march has recently been using in his hospital at Kiel bags of peat-dust impregnated with an antiseptic. This dust is very light and powerfully absorbent of gases and liquids, taking up more fluid, it is asserted, than jute, gauze, or cotton wool—even to nine times its own weight; it is also soft and elastic, and in Germany very easily obtained and inexpensive. The peat may be used alone in bags of muslin, but the more approved method is to have two bags of muslin—one twice the size of the other—purified by being wrung out in carbolic solution, 5 per cent. The smaller is filled with the peat-dust containing 2½ per cent. of iodoform, and is placed immediately in contact with the wound. The larger bag is filled with the peat-dust soaked in carbolic solution, 5 per cent., and this is placed over the other. Such a dressing may remain undisturbed for from several days up to a fortnight, and it is stated that excellent results have been obtained with it. This we do not doubt, but we are unable to believe that this newest form of "antiseptic" dressing will in any way revolutionize surgical practice or become generally adopted.

TUBERCLE OF THE CHOROID.

An interesting discussion took place at the Ophthalmological Society on Oct. 12th, 1882, upon the significance of choroidal tubercle. Examples of the disease were related by Drs. Mackenzie, Warner, and Brailley, and the discussion turned chiefly upon a point raised in the communication of the second-named gentleman—namely, whether the choroidal affection were not more frequently met with as a part of general tuberculosis than in association with tubercular meningitis simply. The question produced some slight divergence of opinion—such experienced observers as Dr. Baxter, Mr. Hulke, and Mr. B. Carter stating that tubercle of the choroid was of extreme rarity in case of meningitis, and therefore the inference is

that much reliance cannot be placed upon it in determining a diagnosis, or rather that its absence proves nothing in the exclusion of a diagnosis of tubercular meningitis. On the other hand, Dr. Barlow mentioned that he had detected it in as many as twenty cases, verified on post-mortem examination. After all, the issue seems to have been a narrow one; for it must be borne in mind that in the vast majority of cases of tubercular meningitis there is tuberculosis of other viscera, and that the meningeal affection is as much a part of the general dissemination of tubercle as is the choroidal. At the same time this fact is plain, that tuberculosis of the choroid no more depends upon tuberculosis of the pia mater than this latter does upon tuberculosis of any other organ. Dr. Sansom's contribution to the discussion was instructive. He cited a case with symptoms of meningitis in which he had given a most unfavorable prognosis because ophthalmoscopic examination revealed choroidal tubercle. The event proved one of three things: either that tubercular meningitis is not necessarily lethal, or that tubercle may exist in the choroid without being present elsewhere to any grave extent, or that the ophthalmoscopic diagnosis of choroidal tubercle is open to fallacy. Which of these interpretations is the most likely must remain undecided, but it is to be regretted that Dr. Sansom had no opportunity of again examining the eye after the recovery of the patient from the meningitis. The attention thus drawn to the subject should encourage investigation into the occurrence of choroidal tubercle, not only as detected by the ophthalmoscope, but as found in post-mortem examination of all cases of tuberculosis.

EXCISION OF THE PYLORUS.

On October 17th, 1882, at St. Thomas's Hospital, Mr. Sydney Jones removed the pylorus for malignant disease. The patient, aged fifty-seven, was under the care of Dr. Bristowe. A large growth completely surrounding the pylorus, together with some affected glands, was removed. The operation was a prolonged one, and was carried out with antiseptic precautions. The patient was much emaciated before the operation, and unfortunately did not rally from the shock, dying about six hours afterwards. We hope shortly to publish the particulars of the operation and morbid appearances.

THE ORGANISMS OF TYPHOID.

MARAGLIANO, of Genoa, has published, in the *Centralblatt für die Med. Wissenschaften*, an important note on the uniform occurrence of organisms in the blood of patients suffering from typhoid. He has found them in the blood of the spleen as well as in that of the general circulation. The blood was obtained by means of a hypodermic syringe, the middle of which was passed through the abdominal wall into the substance of the spleen. Dr. Sciamano, of Rome, first showed that blood may be thus obtained from the substance of the spleen during life without any injurious consequences. The blood of the general circulation was taken from the tip of the finger. In each method every precaution was taken to avoid the accidental introduction of organisms. The examination, in this way, of fifteen patients gave the following result. At the height of the disease the blood of the general circulation contains micro-organisms both isolated and grouped. These consist, almost exclusively, of spherical bodies, which have a delicate contour, appear to be homogeneous, and are analogous to micrococci.

Some of them are mobile. Similar organisms, again, were seen in the blood of the spleen, and in it, too, were others, rod-shaped, also with delicate outlines, perfectly corresponding to those described by Eberth and Klebs. During convalescence these micro-organisms lessen in number in both the splenic and systemic blood. When quinine was given to the patient in large doses the organisms either disappeared from the blood, or were present in it only in small number. The blood from both the finger and the spleen were treated by the method of fractional culture, and a large number of rods were then obtained, similar to those seen in the fresh blood except that some of them were of greater length. The presence of such organisms in the blood of the spleen after death had been previously established by Sokoloff and Fischel, but Maragliano is the first who has demonstrated their presence in the splenic blood during life. He avoids the expression of any opinion as to their relation to the disease.

THE MUNICH ELECTRICAL EXHIBITION.

In addition to a varied display of electricity as applied to technical uses, there is a special branch of the above exhibition devoted to the illustration of the employment of this force in theoretical and practical medicine. In the descriptive remarks which Dr. Stintzing has published on the subject, he alludes to the value of electricity as an exciting medium when judiciously applied to various parts of the human organism, and remarks that electrophysiology has done much to increase our knowledge of the properties and functions of the nervous system, the muscles, the glands, etc. Another important branch of medical science connected with electricity is the diagnosis of certain diseases by means of electrical tests applied to the living body; on which subject he further remarks that physiology teaches us the laws as to convulsive motions, according to which the nerves and muscles are affected by the exciting power of electricity. For instance, if an electrical current (whether constant or interrupted) of a given strength be applied to a nerve, the muscles with which it acts are excited and become contracted according to fixed laws. In these involuntary reactions of the organs of motion upon the electrical current it makes a difference whether the latter passes through the nerves in an ascending or in a descending direction, and whether the action of the positive or negative pole preponderates. When the body is diseased, these physiological laws are subject to changes, and by carefully noting the deviations from the general rules which may be observed in the application of the electrical current in different ways to sick persons, conclusions may be drawn of practical value in the diagnosis and prognosis of such cases and in the regulation of the most suitable form of treatment for them. Electro-diagnosis and electro-therapeutics go hand-in-hand, and the exhibits at Munich affecting medical electricity illustrate both subjects; the appliances connected with the former being of course the more complicated. The Munich Medical and Clinical Institute and various manufacturing firms exhibit instruments of great exactness for ascertaining and regulating the force of the electrical current. A great variety of instruments and appliances of a portable form, suitable for general use by medical men, are also exhibited, including batteries, communicators, wires, etc., constructed with special reference to the different models which the various parts of the body require for the successful application of the electrical currents. For electro-therapeutical purposes the accurate measurement of the strength of the

electrical current is indispensable, and the simple yet effective galvanometers for this purpose, made in two sizes by Dr. Edelmann, of Munich, at the suggestion of Professor von Ziemssen, are highly spoken of. In contrast with the use of electricity, as applied by means of batteries and inductive appliances, the employment of electricity obtained by friction has been specially recommended of late by Dr. Stein, of Frankfurt, and various instruments, etc., required for the application of this method are exhibited by Messrs. Albert, of that city. The photographs illustrative of the effects of electricity upon the nerves and muscles, and other representations showing the muscles, or groups of muscles, most easily effected by the electrical current, are interesting adjuncts from a medical point of view. Dr. Stintzing also refers to an electro-endoscopic apparatus, which is applicable to diagnostic purposes. It is intended for the partial illumination, by electrical means, of the ear, nose, jaws, and other portions of the human body. In the same category mention is made of two small endoscopic instruments exhibited by Dr. Michael, of Hamburg, in which phosphorescent substances are subjected to the influence of an electrical discharge.

THE HARVESTING OF ICE.

THE season has again come round when large quantities of ice are collected and stored with a view to its being used during the summer months in connection with our food supplies. Some of it is actually mixed with foods and drinks, more still is brought into close contact with such articles of diet as fish, poultry, butcher's-meat, etc., in order that it may act as a preservative. Unfortunately, however, but little regard is had to the sources whence the supply is derived, and after every frost, carts laden with ice which has been collected from the surface of ponds, canals, and streams which would be studiously avoided as water-supplies, may be seen passing along our streets to the shops of tradesmen dealing in articles of food and drink. That the use of such ice for the purposes to which it is put is not without risk has been shown both in this country and more especially in America, where in the warm weather ice enters largely into the list of table requisites; indeed, it has been further proved that ice has acted as the vehicle of disease germs capable of conveying enteric and scarlet fever, and its use has also been associated with conditions of ill-health which have much resembled these and other specific fevers. The carelessness which has obtained in selecting sources for the collection and storage of ice has been largely due to the fact that there is a very general opinion that in the act of crystallization water practically rids itself of all its injurious qualities, however offensive it may be in its liquid state, and acting on this view, it is notorious that ice for domestic use has been, and still is, collected from streams receiving sewage, ponds that are offensive in summer time with decomposing vegetable growth, and similar sources. There is also a sufficient amount of truth in the general opinion as to the process by which noxious and foreign matters are eliminated from water during the act of freezing to lead to some lack of caution on the part of the uneducated, but recent experience has clearly shown that the process of purification is only a partial one. In connection with this subject an interesting paper comes to us from across the Atlantic in Dr. Wight's First Annual Report to the Board of Health of Detroit, and it includes a copious reference to certain recent experiments by Mr. C. P. Pengra, an analytical chemist. In the first instance, urea, as a representative of the crys-

taloids, was mingled with water, which was then frozen; and it was found that whereas 100 cubic centimetres contained 0.83 gramme before freezing, they still retained 0.50 gramme when in the form of ice. Very similar results followed in experiments made with urea as found in urine, and with other substances, such as grape sugar. The next experiment was with the colloids; albumen, both from the egg and from a case of albuminuria, being taken as a sample, and it was shown that the amount retained in the frozen mass was greatest at its under, and least at its upper, surface. Thus 50 cubic centimetres from the lower third contained 6.87 grammes, the same quantity from the middle and upper thirds containing 4.19 grammes and 3.0 grammes respectively. Other experiments with the same material showed that the purification which did take place amounted to about 20 per cent. of the total admixture. The results would doubtless vary according to such circumstances as the rapidity of freezing, but since in all the instances recorded the specimens were frozen naturally, they amply suffice to show, as the author contends, that pure ice can only be procured from water free from impurities, and that ice for domestic purposes should never be collected from ponds or streams which contain animal or vegetable refuse or stagnant and muddy contents.

FLOORING AS A MEDIUM OF INFECTION.

THE *Zeitschrift für Biologie* lately published a statement on the above subject from the pen of Dr. Emmerich, of Leipzig, in which it is remarked that notwithstanding the attention paid to disinfecting walls, furniture, bedding, and clothing after illness of an infectious character has taken place in a house, the danger from the flooring, though usually neglected, is no less real than that which might arise from any of the sources enumerated. The material used in filling up flooring is often of a nature, it is urged, capable of itself producing, under certain circumstances, emanations of a noxious character. Should, however, even quite harmless materials have been used for the purpose indicated, it is argued that while a house is inhabited there is a gradual accumulation of organic substances going on which penetrate through the openings in the flooring. The constant washing tends, it is said, to make the filling damp, and in addition to this source of danger the temperature under the flooring is often higher than that of the room itself, it having been demonstrated that when the temperature of a room has been 61° Fahr., that of the space underneath the boards has been as high as 90°. This has apparently been specially the case in the vicinity of a stove. This fact is referred to in connection with the theory held by Dr. Koch that a temperature of 90° is necessary for the development of bacilli, the existence of which he has demonstrated. This temperature as a normal one was found by him not to exist in connection with our daily surroundings. In addition to dry rot, which is not without an influence on health, Dr. Emmerich found in numerous samples of the filling used underneath flooring quantities of bacteria. That other substances of a noxious character were present was likewise proved by the fact that Dr. Emmerich and his assistant became ill whenever they had been engaged in protracted investigations of this kind. It is evident that if infection lurks in the flooring, the most thorough measures of disinfection which may be taken as regards other portions of a room may fail to restrain the spread of disease. This explains how illness has been found to originate in one room of a house, or even in certain portions of a room. A mouldy smell in a room after it has been

washed is said to be in some measure an indication of the existence of the state of things which has been described. It is, however, remarked that the absence of such a smell must not be taken as conclusive proof of the room being free from any such noxious influences from underneath, as earth has the property of checking the bad odor of decaying organic matter without, however, arresting the process of decomposition. The practical recommendations of Dr. Emerich consist for the most part of suggestions for the prohibition of the employment as filling material in new buildings of any substance containing phosphorus, potash, or magnesia; it being remarked incidentally that they are notably abundant in coal-slag. For houses already inhabited, he recommends that the inner portions of the flooring should be shut off by an air-tight and water-tight substance from any communication with the air of the room itself. It is further suggested that divisions between the boards should be avoided as much as possible, and that the boards themselves should be coated with some water-resisting substance in order to render them impervious to the influence of moisture.

AN "EDITION DE LUXE."

We have received from Messrs. Sampson Low & Co. a copy of the first volume of Dr. Francis Delafield's "Studies in Pathological Anatomy," published by Messrs. Wood & Co., of New York. This work, which has, we believe, been several years in preparation, is produced in a style that does great credit to both the author and publisher. It forms a large handsome quarto, admirably printed as to the text, and contains no fewer than ninety-three plates illustrative of the histological changes in inflammation of the connective tissues, serous membranes, and lungs, and also of tuberculosis, a large number of plates being devoted to acute phthisis. Some of the plates are lithographs of camera-lucida drawings; others are photographs of microscopical preparations. We shall have occasion to comment on this work when we have more thoroughly examined it; but meanwhile we may congratulate Dr. Delafield upon its appearance, and trust that he will continue the undertaking according to the plan he has marked out for himself, which must take many years to complete.

APPOINTMENTS OF HEALTH OFFICERS.

We are glad to record the reappointment of Mr. E. L. Jacob as medical officer of health for the Surrey United Sanitary District. In the nine years during which Mr. Jacob has held this appointment he has performed the duties attaching to his office with singular success. During periods of comparative healthiness, he has inaugurated and steadily pressed on sanitary measures with a view to a still further improvement in the health of the inhabitants. Whenever any special incidence of disease has manifested itself, he has been indefatigable in tracking it to its source; and his reports, both as to such occurrences and as to the general sanitary circumstances of his district, have always been such as to command confidence in the remedial measures he has recommended. The *Surrey Advertiser*, the leading paper of the county, emphatically corroborates the above testimony. Owing to the fact that Sutton has somewhat recently been converted into an urban district, the appointment to this parish will have to be effected separately, but we hope that no effort will be made to detach this place from the united district which Mr. Jacob has held up to the present. Both in his and other districts we are glad to note a recommendation from the Local Government Board to

the effect that medical officers of health who have successfully served their districts should be reappointed for comparatively long terms. In the case of the Surrey combined district the recommendation extended to a term of ten years, and though the authorities in this instance only made it for six years, yet the principle involved in thus making the office of a health officer secure for a number of years is one which we are glad to see carried out. Many such officers have found themselves seriously hampered by the knowledge that at frequently recurring and short intervals they would be compelled to submit to re-election, and the practice has not only prevented the commencement of permanent works of improvement in many districts, but it has deterred many competent men from joining the medical sanitary service. The step taken is one in the right direction, and it is probably the first instalment of a more complete recognition by the central authority of the proper status of a medical officer of health.

THE NUTRITIVE PROPERTIES OF RICE.

THE increase in the consumption of rice has lately attracted the attention of several men of science in Germany, and amongst other investigations, an attempt has been made by Professor Voit to discover the relative capacity which various forms of nourishment possess of being incorporated into the system. He has drawn up the following table of the percentage which remains in the body, and of that which leaves it:—

	Percentage incorporated.	Percentage which is not retained.
Meat.....	96.7	3.3
Rice.....	96.1	3.9
Eggs.....	94.8	5.2
White bread.....	94.4	5.6
Maize.....	93.3	6.7
Potatoes.....	90.7	9.3
Milk.....	88.9	11.1
Black bread.....	88.5	11.5

According to these results (the *Bremer Handelsblatt* remarks) meat and rice leave the smallest amount of residuum, and occasion the smallest excessive exertion to the digestion, and in fact introduce the minimum quantity of ballast into the human frame. Dr. König, of Münster, considers that the fact of large masses of population living on rice is easily accounted for, and in summing up the information collected upon the subject, Professor Voit remarks that potatoes, when consumed in excessive quantity, fail to nourish the frame effectively, make the blood watery, and render the muscles weak. Apart from the subject dealt with in the table drawn up by Professor Voit, the question of the relative nutritive value of rice and potatoes has been investigated by Dr. König, who is of opinion that if similar quantities of both articles are compared, the former possesses four times the value of the latter in really nutritive properties. It is also remarked that the introduction of rice as a substitute for potatoes is facilitated by the fact that no such variation takes place in its quality as is the case with the potato, which is liable to be materially influenced by the effects of unfavorable weather.

THE REFUSAL OF OUT-DOOR RELIEF.

THE iniquity—we can use no less opprobrious epithet—of the "workhouse test" is becoming one of the crying sins of this rich nation. If we were fatalists we should say it is one of the devices by which the gods are dementing us; let us rather say by which political economists of the advanced school are dragging this country down to

the depths of social confusion and consequent obscurity. The workhouse test is an offence against humanity—a hideous folly unworthy of men with brains, to say nothing of hearts. Can anything be more unnatural or inhuman than to refuse poor married folk struggling against pauperism the help of a crust unless they will go into the workhouse and consent to be torn asunder at the moment when their lives are on the wane, and when the only particle of happiness left them at the fag end of a luckless existence is to go to the grave hand in hand. It is hard to write temperately of such brutality as is smirched over the glamor of political economy in this device. We have heard enough to freeze the blood in our veins of the encouragement offered to idleness by what has been held up to reprobation as “indiscriminate almsgiving.” Let us tell those who originate and flaunt this phrase in the face of Englishmen that it is offensive to the first instincts of our nature. The cold calculating spirit which sits down to tottle up its figures to prove that beggars are encouraged by giving them alms, has found its fruition in the “workhouse test.” There is no humanity, no true philanthropy, underlying this crazy cleverness. Give to the poor!—on their heads be it, not on ours, if charity is abused. Let the struggling creatures who are striving to keep out of the “house,” who do not wish to be wholly dependent, who have a scrap of self-respect still left in them, be helped to live, not left to die. We appeal to the ratepayers of this country to say, when next the election of guardians occurs, that not one man shall be returned who will refuse outdoor relief to the poor. Make the relieving officers and the overseers do their work, and see to it that the public money is not wasted on impostors; but let it once for all be understood that the ratepayers of England will not permit the funds they subscribe for Poor-law purposes to be so administered that the black crime of letting honest and true-hearted couples die because they will not be separated lies at their door.

NEW HUMAN ENTOZOOON.

A few weeks back it was announced in our columns that Dr. Patrick Manson, who is now in England, had detected a curious cestode in the human body. He found twelve parasites in the subperitoneal fascia and elsewhere. How they came there is a matter of opinion, but under the name of *Ligula Mansonii* the worm was described by Dr. Cobbold at the last meeting of the Linnean Society. The author of the paper stated that probably the infested Chinese had drunk from a pond frequented by water birds infested by ligules, whose immature stages of growth are passed within the fishes living in the same ponds. Dr. Cobbold alluded to the destructive effects of ligules amongst the tench living in the ponds of La Bresse. He pointed to the circumstance that Italians were accustomed to eat fish-tapeworms under the name of *macaroni piatti*, and he expressed the belief that Dr. Manson's patient had swallowed the ciliated embryophores and their contained proscolices which had thus strayed and bored their way into the man's tissues. It is satisfactory to know that they had no concern in the production of the human victim's death.

A HEAVY BRAIN.

It is well known that, although many distinguished men have had very large brains, these have been occasionally equalled by the brains of persons who never displayed remarkable intellect. Another illustration of this has been lately pub-

lished in the *Cincinnati Lancet* by Dr. Halderman, of Columbus. A mulatto named Washington Napper, aged forty-five years, recently died in the hospital at that town in consequence of purulent infection due to an abscess of the thigh. His brain was found to weigh 68½ oz., nearly 5 oz. more than the famous brain of Cuvier. His height was six feet, his limbs are said to have been ape-like in length, his head was massive, lips thick, lower jaw prominent, but his forehead large and well developed. He had been a slave until the year 1862, and had never been regarded as particularly intelligent; he was illiterate, but is said to have been reserved, meditative, and economical.

FACE POWDERS.

It is necessary to raise a warning cry against a most mischievous statement which has recently been circulated, and has already done harm, to the effect that “arsenic in small doses is good for the complexion.” It is not difficult to imagine the risks women will incur to preserve or improve their “good looks.” No more ingenious device for recommending a drug can be hit upon than that which the authors of this most baneful prescription of “arsenic for the complexion” have adopted. Suffice it to recall the fact that for many years past chemists and sanitarians have been laboring to discover means of eliminating the arsenical salts from the coloring matter of wall-papers, and certain dyes once largely used for certain articles of clothing. It is most unfortunate that this hopelessly antagonistic recommendation of arsenic to improve the complexion should have found its way into print. Those who employ the drug as advised—and there are many either already using it or contemplating the rash act—will do so at their peril. So far as they are able, however, it will be the duty of medical men to warn the public against this pernicious practice, which is only too likely to be carried on secretly. It is not without reason that we speak thus pointedly, and urge practitioners to be on the *qui vive* in anomalous or obscure cases.

PASTEUR ON RABIES.

At a recent meeting of the Académie de Médecine, M. Boulay communicated, in the name of M. Pasteur, a series of conclusions regarding rabies at which the distinguished investigator has arrived. The first two enunciate the familiar truths that the dumb madness and furious madness, and, in short, all varieties of rabies, are caused by the same virus, and that the symptoms of rabies are extremely variable. It is assumed that the characters of the several cases depend on the points in the nervous system at which the effect of the virus is chiefly localized. In the saliva of rabid animals the virus is associated with several kinds of organisms, and the inoculation of the saliva may cause death in three ways: by means of the special salivary organisms, by excessive suppuration and by rabies. The medulla oblongata of the human subject, as well as that of animals, after death by rabies, is always virulent, and the virus is also found in all parts of the brain, and it persists even after putrefaction has set in. There are two methods of inoculation by which the period of incubation of rabies may be greatly shortened, and the disease produced not only rapidly but with certainty: one is by the injection of the virus into the blood; the other is by trephining the skull and placing the virus in the arachnoid cavity. Rabies then comes on at the end of six, eight, or ten days. M. Pasteur has met with some cases of the “spontaneous cure” of rabies, but only in cases in which

the disease did not develop beyond the initial stage. In such a case, in which the early symptoms passed away, the disease has been known to return at the end of a certain time—as two months—and then to run the ordinary acute and fatal course. Mention is also made of the cases of three dogs inoculated in 1881: two quickly died from rabies; the third, after manifesting the early symptoms, recovered. The latter animal was inoculated by trephining in 1882 on two separate occasions, but without effect. M. Pasteur asserts that he now possesses four dogs which will not contract rabies, whatever the method of inoculation adopted or the proved virulence of the material employed. These facts he believes to be the first step towards the discovery of a method of the prevention of rabies by its inoculation. He confesses, however, that the end seems to be at present far distant.

LISTERISM IN ITALY.

LISTERISM grows in favor in Italy, if we are to judge from an article "On the Foundations of Modern Surgery," just published by Professor Andrea Ceccherelli in the *Gazzetta degli Ospitali* (Milan, Dec. 13th). The author is a firm believer in the clinical potency of micro-organisms, and extols antiseptic dressings as amongst the greatest of modern surgical conquests.

Correspondence.

"Audi alteram partem."

NEW YORK.

(From our Correspondent.)

THE announcement is made that the German Government have prohibited the importation of American pork at the ports of Germany. This once more revives the question as to the relative danger of using American hog meat, and as I have watched the subject on this side for some years, I will offer your readers such facts as I have gathered. The common policy of all interested in the exportation of pork from the United States is to deny that trichinæ exist in American hogs; this statement is generally endorsed by the newspapers, and even to some extent by Government bureaux. The many Chambers of Commerce throughout the country and those who deal in the article preserve a safe silence and inaction. Statistics therefore from such sources are not forthcoming, and the difficulty is great when an attempt is made to prove the truth of the various statements. The only reliable inspection of hog meat for trichinæ which has been made in the United States, was once made at Chicago under the auspices of the Board of Health by two microscopists. I believe about two thousand hogs were examined, the result being that eight per cent. were found infected with trichinæ. Such a high percentage certainly invited a closer consideration of the subject, but no steps were afterwards taken either to prove or disprove the result of this single examination. Cases of trichinosis occur in the United States at rare intervals. The last case brought to my personal notice was that of a family at Erie, Pa., where a family of five persons was attacked. The attending physician attributed the trouble to typhoid fever, supposed to have been caused by a well, but Dr. Ed. W. Germer, the health officer of the

city, solved the mystery by finding trichinæ in pork of which all the patients had eaten. A portion of the psoas muscle was forwarded to me, and from sections made by myself I could display ten to twelve trichinæ in the field of the microscope at one time. The pig in question had been raised by the family, and it was clearly a case of trichinosis due to a native hog. Curiously, another pig had been raised in the same sty; they had been fed with the same food, and reared under similar conditions. Both were killed at the same time, when one was found to be infested with trichinæ, while the other was perfectly free from that parasite. A few weeks later, Dr. E. C. Wendt, of Hoboken, N. J., reported the fatal termination of a case of trichinosis, attended by Dr. W. T. Kudlich, of that city. In this instance a robust young married couple were attacked by trichinosis, the case of the woman terminating fatally. Dr. Kudlich stated that the disease was unmistakably traced to home produce. On this occasion some interesting experiments and observations were made with the trichinæ found in the unfortunate woman's body. None were found encapsulated, but some had assumed the spiral form, or the preparatory stage, but the majority were free, and either stretched out or twisted at either extremity. Little pieces of the woman's muscle were exposed to cold, and even frozen several times. After four days of such exposure an examination found them quiescent; but a gradual elevation of the temperature to 100° F. caused them to show active motion, and ten days later these parasites were still alive. Thirteen days after the death of the woman some of her muscle was allowed to undergo putrefaction, but the trichinæ still lived. On the day following the autopsy some of the fresh muscle was teased, and there being abundance of trichinæ many became isolated; these were never found to creep along in a definite direction, but some were seen to move in a manner to resemble the unfurling and recoiling of a pennon, and a change of place was sometimes fortuitously effected. Dilute acids increased their motion, and alkalies had a contrary effect, while concentrated solutions of both rapidly killed them. In carbolic acid they squirmed and writhed before dying. Glycerine did not immediately kill them. A little fresh muscle was submitted to artificial digestion by being placed in a suitable fluid and exposed for twelve hours to about body heat. The muscle was in great part dissolved at the end of this time, and many free parasites were found in the liquid. They were, if anything, less active than they had been, and as the liquid cooled their movements ceased, but were renewed on re-heating the slide. During this period of experimenting, a noteworthy fact of interest was observed, that the trichinæ had grown. Dr. Wendt on this occasion made the observation on the diagnostic value of examining small pieces of muscle from accessible regions in patients suspected of trichinosis. If the parasites were found, the evidence was of course incontrovertible; but he added, if *vice versa*, a conclusion could not be arrived at. In the present fatal case of trichinosis, small bits of the deceased woman's muscle were torn from the gastrocnemius and deltoid muscles; and while some specimens contained numerous parasites, others were found without them. In the diaphragm, intercostal muscle, and other well-known places of predilection, every examined specimen showed abundant parasites. In regard to the prevalence of trichinosis in the United States, medical statistics cannot be relied on; as Dr. Satterthwaite, President of the New York Pathological Society, observes, although a vast amount of labor has been expended on the origin, clinical history, and treatment of trichinosis, we have

good reason to believe that it is seldom recognized during life, and even after death escapes notice, unless the examiner has his attention specially directed towards the possibility of its occurrence. Cases of trichinosis are certainly very often found in the dissecting-rooms and deadhouses. Dr. Carpenter's observation at the dead-house of the Bellevue Hospital has been that the encysted trichinæ are found more frequently in the pectoral muscles or the diaphragm than in the deltoids or the gastrocnemii. It is with the Germans only, who persist in eating raw ham, that trichinosis is found; others who thoroughly cook their meat appear to preserve immunity from contagion. I believe the result of the Chicago examination of pork showing a percentage of 8 per cent. of infected pigs to be perfectly unreliable as a test of the extent of the contagion among American hogs, and that if proper steps were taken to obtain trustworthy statistics a condition of American hogs could be shown which would inspire confidence for this stable article of food in foreign countries. I do not desire to discredit the work of the Chicago microscopists, but I maintain that a single test is valueless. What I desire to see is the result of daily examination carried over twelve months; with such statistics a sound average could be presented.

New York, Dec. 2nd, 1882.

DR. HENEAGE GIBBES' "NEW METHOD FOR THE DETECTION OF THE TUBERCLE BACILLUS."

To the Editor of THE LANCET.

SIR—At a meeting of the Medical Society of London on the evening of Dec. 22nd, Dr. Heneage Gibbs exhibited some specimens of various forms of bacteria. Amongst them were several examples of the bacillus of tubercle stained in a way which Dr. Gibbs has described as "new." In the course of some remarks which I made during the meeting, I expressed my inability to perceive anything new in the method of staining the bacillus of tubercle used by Dr. Gibbs. I also said, in effect, that in the specimens of the bacillus of tubercle then before the Society I could not see evidence of any advantage in the results obtained by Dr. Gibbs' plan of mixing the ingredients of the coloring solutions in certain definite proportions. In describing what he claims as his method, Dr. Gibbs says: "It is necessary to make two staining fluids—one, magenta, which stains the bacillus; the other, chrysoidin, which stains the surrounding substance but not the bacillus." Now, on reading this, it certainly appears as though in using magenta Dr. Gibbs has introduced a new dye for the purpose of staining the bacillus. As is well known to those who are familiar with the subject, Dr. Ehrlich uses fuchsin for that purpose. I had always been under the impression that fuchsin and magenta were different names for the same substance. When Dr. Gibbs described his "new" method and spoke about magenta, I thought that I must have been in error, and that fuchsin and magenta were names for two different substances. On looking up the literature of the subject, however, I found that these two names are given to one and the same substance. In order to put the point beyond dispute, as regards the use of the dye in the staining of this particular bacillus, I called upon Mr. Beck, the manager of the Badesche Anilin Fabrik, 22 Bush-lane, Cannon-street, E.C. I called upon him because Dr. Gibbs says that the aniline colors are made by that company. Mr.

Beck, in answer to my question, told me that fuchsin and magenta are names given to one substance. He said that if he received an order for magenta he would supply the same substance which he would supply were an order given for fuchsin. Fuchsin he said, is the name used on the Continent, magenta is the name in use in England. I was also told that the substance supplied by Mr. Beck to Dr. Gibbs was known in the trade by the two names, fuchsin and magenta. Mr. Beck said that Drs. Koch and Ehrlich used this same dye in their experiments. In April last Dr. Ehrlich used fuchsin to stain the bacillus of tubercle, and my friend, Dr. Koch, the discoverer of the bacillus, described to me in a letter last May the details of Ehrlich's use of fuchsin in this connection. So much then for Dr. Gibbs' stain for the bacillus in his "new" method.

It not necessary for me to say anything here about Dr. Gibbs' use of chrysoidin in his "new" method, for that night he himself informed the Medical Society that he had given up the use of that substance in staining tubercular tissue and sputum, although, he says, he still regards chrysoidin as most useful when the object in view is merely to examine the bacillus. In saying this I, of course, speak from memory; but that was the sense in which I understood what fell from Dr. Gibbs upon this point.

Having given up the use of chrysoidin for the purpose of staining "the surrounding substance, but not the bacillus," Dr. Gibbs has substituted methylene blue for it, as was seen in his specimens. In the *British Medical Journal* of October 21st last, on page 787, under the heading, "Further Remarks on Staining Bacillus Tuberculosis," Dr. Gibbs writes: "I have made a number of experiments with the view of finding a good contrast to the magenta, and one which would not at the same time stain the surrounding tissues too deeply. I find methylene blue the best for this purpose." Now, at my demonstration at Worcester, in August last (and Dr. Gibbs was present), I pointed out that Ehrlich used methylene blue as a contrast color to his red-stained bacilli¹. The fact was also known to several men who were then working at Ehrlich's process, and it was mentioned to me by Dr. Koch in May last.

Where, then, is the newness in Dr. Gibbs' "new" method? I suppose it is meant to be found in the statement which he makes on page 787 of the *British Medical Journal* of Oct. 21st, where he says, "There are one or two points about this method which I should like to mention. In the first place; the magenta solution used is a definite chemical compound having a distinct formula; it is, in fact, a diphenolrosanilin resulting from the addition of a fixed portion of pure anilin to a certain form of rosanilin, or, as it is commonly called, magenta. In Ehrlich's method, a definite compound is not formed, hence the fading of the color from the bacilli, which does not take place when a stable compound is used. In his process, also, the protoplasm alone is stained, and with high powers rows of bead-like bodies only are seen. With the method I have given, the whole organism is stained, and appears, as it really is, a rod-shaped bacillus containing deeply stained spherical bodies (?spores)." I do not know whether a diphenolrosanilin results; but let that be taken for granted. Of the rest of this statement, in so far as it refers to Ehrlich's process, I can only say that it is altogether at variance with my own experience. I have not yet seen a specimen of bacilli produced by that process in which "with high powers rows of bead-like bodies only are seen." On the con-

¹ *British Medical Journal*, Oct. 14th, 1882, p. 736.

² *British Medical Journal*, Oct. 14th, 1882, page 735.

trary, the vast majority of the organisms appear as distinct rods.

Dr. Gibbs asserts that with his "new" method the color does not fade from the stained bacillus, and that it does fade where Ehrlich's process has been used. It is true that when men first worked at this process the stained bacilli did, now and then, lose their color. In my own early experience that has happened more than once. It is different now. Ehrlich's process, properly carried out, gives quite as good results as any yet shown by Dr. Gibbs. As an illustration I may mention that I have now in my possession specimens which I stained by Ehrlich's process in June last for exhibition at the conversazione at the Royal College of Physicians. They have faded certainly, as all aniline colors will, but the organisms are still perfectly distinct. As M. Vignal, of Paris, remarked in writing upon this subject, "When the chemicals are not good, the color fades with equal rapidity, whether Gibbs' modification be adopted or not."

Dr. Gibbs also claims for his "new" method that by its use the bacillus can be shown "with the greatest ease with an ordinary quarter-inch object glass and daylight." According to him, where Ehrlich's process is used the bacillus is so faintly stained "that high power or artificial illumination is required to show it in anything like a satisfactory manner." This is another example of Dr. Gibbs' surprising statements. My friend, Mr. Watson Cheyne, showed the bacillus, prepared by Ehrlich's process, in May last at the Royal Medical and Chirurgical Society, under a quarter-inch object glass. I have myself repeatedly examined the bacillus under an ordinary quarter-inch object glass, and with very ordinary London daylight as my only illuminator.

It is not very surprising to find that Dr. Gibbs has so poor an opinion of Ehrlich's process when one reads his description of it on page 736 of the *British Medical Journal* for Oct. 14th. It runs thus: "In Ehrlich's process the stain for the bacillus is too faint, and the vesuvin used to stain the ground substance too opaque; consequently the bacillus appears a faint pink color on a dense yellowish-brown ground, and is not easily made out without high power or special illumination." If with Dr. Ehrlich's process the staining of the bacillus is found to be too faint, the fault will lie with the experimenter and not with the process. In August last Dr. Gibbs evidently did not know what was meant by Ehrlich's process, else he would surely never have said that at that time, or for months before that time, Dr. Ehrlich used vesuvin to give a "dense yellowish-brown ground," to a bacillus of a "faint pink color." Since April last Dr. Ehrlich has used methylene blue as a contrast color for red stained bacilli.

I am, Sir, yours faithfully,
G. A. HERON.

London, Dec. 5th, 1882.

ON EXAMINING THE SPUTUM IN LUNG DISEASES OR THE BACTERIA OF TUBERCLE AS A MEANS OF DIAGNOSIS AND PROGNOSIS, AND SOME REMARKS ON STAINING.

To the Editor of THE LANCET.

SIR—I have lately used as a means of diagnosis of tubercle an examination of the sputum for tubercle bacilli in all my cases of lung disease where grounds for suspicion existed, and I have found such means of diagnosis very valuable, in many cases solving the question where auscultation gave merely negative evidence. In two cases of apparently chronic pneumonia the discovery of

bacilli in the sputum of one and not in the other led to a decided diagnosis and a variation of treatment, which was afterwards completely established by the subsequent progress of the cases, for in the one decided symptoms of phthisis became established in one lung, and in the other the lung trouble completely cleared up; and if the theory concerning the existence and connection between these bacilli and tubercle be correct we cannot too highly estimate the value of the means that the existence of these bacilli affords of forming a correct diagnosis and a consequent prognosis, which is so anxiously looked for by the friends in these cases. I have used the methods of Ehrlich and Heneage Gibbs, but find the latter's method the easier to follow, and at present use that solely. I prefer, however, that the secondary staining be done in methylene blue instead of chrysoidine; the surrounding tissue is rendered more distinct, whilst the contrast between the red bacteria and the blue is greater than between the red and brown of the chrysoidine.

I regret to say that when I first used either method my attempts were failures for a long time, and I began to almost give up in despair when it occurred to me that at the time the methods were described the weather was very warm, and I discovered that the cover-glasses when in the magenta solution should be kept at a temperature of 100° F. This I found ensured a uniform and deep crimson stain to the bacilli, so that in the sputa, examined previously without any result, I now found plenty of bacilli, and on obtaining fresh sputa I found them at once. The bacilli of putrefaction are not stained by this process, but in specimens which have passed through the nitric acid process and been washed, the putrefactive bacilli may be well shown by staining with a solution of gentian violet without affecting the tubercle bacilli—thus demonstrating the two kinds, and proving that they are not identical. I find also that for rapid work and purposes of diagnosis, the cover-glass may, after staining in methylene blue and washing in water, be dried at once over a spirit-lamp flame, and mounted in a solution of Canada balsam, in chloroform and benzole, and examined at once. I have specimens prepared in this way two months ago in which the bacilli can be easily discovered by any one, even if not an experienced observer. They may be clearly seen with a No. 6 Hartnack, or even a quarter-inch, and with the former the spherical bodies within them are easily distinguished. I thus dispense with the washing in absolute alcohol and drying in the air. It is also necessary that the washing after staining should be done with distilled water. I find the dyes obtained from Martindale are quite stable, and my preparations have not faded at all as far as I can judge.

I am, Sir, your obedient servant,
ENGLEDUE PRIDRAUX, L.R.C.P. Lond., etc.

Wellington, Somerset, Dec., 1882.

HAMAMELIS VIRGINICA.

To the Editor of THE LANCET.

SIR—*Hamamelis virginica* is an indigenous American shrub, growing chiefly in the New England States. It has been used by the laity as a domestic remedy in various complaints since very early times. It was first noticed in regular medicine by Dr. Fountain in 1848 (*New York Journal of Medicine*), and a year later by Dr. N. S. Davis (*Transactions of the American Medical Association*). It was recommended by these gentlemen as a remedy for hæmoptysis and hæmorrhoids, taken internally for the former and used locally and internally for the latter. These notices fell dead, and for many

years nothing further appeared on the subject except in the advertisements of a remedy known as "Pond's Extract of Witch Hazel." This preparation is not, pharmaceutically speaking, an extract. It is in reality a distilled water, obtained by distilling the bark of the young twigs with water and adding alcohol to the distillate to preserve it from decomposition. Since the introduction of this preparation numerous imitations of it have appeared, and I presume the hazeline of the English market is one of them. Your correspondent, Mr. Symes, speaks of this as being "the active principle of the witch-hazel." This is unquestionably not the case. Thus far no active principle has been isolated. That hamamelis contains an active principle is undoubted, but thus far no one has been able to obtain it, although a great deal of time and money have been expended on the research. We simply know that it is not an alkaloid, glucoside, resin, or resinoid, but what it really is remains as yet a problem. The plant itself is of considerable commercial importance, and a good deal of capital is invested in the manipulation of it. One firm, for instance, manufacture a "concentrated extract," which they sell to dealers, who dilute it with alcohol and water and then place it on the market under various names. I presume hazeline is one of these, but cannot speak with certainty, as there is no preparation with this particular name on the American market.

Hamamelis is officinal in the new U. S. Pharmacopœia (1882), and official directions are given for the preparation of a "fluid extract." The writer has been familiar with the uses and virtues of hamamelis for many years, has made some fruitless chemical investigations as to the nature of its active principle, is one of the "Committee of Revision" of the Pharmacopœia, and believes that the official preparation is the one that will give the most satisfactory results in practice.

I remain respectfully yours,

HENRY G. PIFFARD.

New York, Nov. 16th, 1882.

HYSTERICAL IMITATION OF THE EFFECTS OF ETHERIZATION.

To the Editor of THE LANCET.

SIR—A curious hysterical condition that came under my notice Nov. 30th, 1882, is, I think, unique.

The patient was a young lady, about eighteen years of age, and had to undergo an operation in connection with the mouth. It was arranged that this should take place under the influence of an anæsthetic. About three years and a half ago I had administered ether to this patient, and some teeth had been extracted while she was under its influence. Hysterical laughing and crying preceded the return to sensibility, and this condition lasted for several hours. On the morning of Nov. 30th I poured some ether into a cone, which I held for a second or two about three inches from my patient's mouth, so that she might get accustomed to the smell, this being a practice I am in the habit of adopting before pressing the cone on to the face. She could have scarcely recognized the odor when I was struck by her peculiar appearance, and I therefore placed my cone upon a table that was near to me and watched the strange hysterical condition that ensued. First the eyelids quivered with great rapidity and there was a strong convergent squint, the face becoming congested and assuming that purple tint so common in the early stage of anæsthesia. Then followed violent trembling of the upper and lower limbs, succeeded by strong convulsive struggles, and lastly com-

plete muscular flaccidity, with heavy breathing. I could now touch the edge of the upper eyelids without producing reflex action. The time occupied by these successive stages was from two to three minutes, and no ether was inhaled beyond such whiffs as might have reached the patient while the cone was three inches away from her mouth. The moment I replaced it she became sensible, and it was with considerable difficulty, and after the expenditure of seven ounces of ether, that I produced insensibility. When the operation was over violent hysterical crying came on and lasted for more than three hours. I am, Sir, your obedient servant,

JAS. GODFREY THRUPP,

Formerly Etherist, etc., St. George's Hospital.
St. Stephen's-road, W., Dec. 5th, 1882.

"PERFORATING ULCER OF FOOT AND LOCOMOTOR ATAXY."

To the Editor of THE LANCET.

SIR—Out of three well-marked cases of locomotor ataxy which I have had considerable opportunities of observing, one had an intractable abscess situated over the outer tarso-metatarsal joints of the left foot on the dorsum. This was open for the last two years of the man's life. It certainly could not come under the title of perforating ulcer, but I always connected it with the nerve affection in my own mind.

I am, Sir, yours, etc.,

E. E.

October 30th, 1882.

VACCINATION.

To the Editor of THE LANCET.

SIR—There really seems no limit to the aspects of the vaccination question. Now comes an ethical one. As small-pox has recently made its appearance in more than one of our African colonies, and is spreading rapidly among the colored populations, the point may not be unworthy of attention.

Dr. Tinsley, a well-known practitioner of the Island of Cuba, alleges that vaccine virus after passing through the negro's system is rendered prophylactically valueless for the race. If there be any grounds for such a view, it would be well to ascertain whether the Negroid Hottentot, Kaffir, and such like dusky peoples of South Africa, ought to be included, or to what extent.

It is to be hoped that in such a negative inquiry as is suggested, observation would prove more edifying than in the positive one with ourselves. In any case, should we fail to learn how far Dr. Tinsley's conviction is supported by fact, there would be something gained in knowing if his opinion was shared by those as favorably situate as himself for judging in the matter.

I am, Sir, yours, etc.,

A. M. BROWN, M.D.

Keppel-street, Russell-square, London, Dec. 13th, 1882.

VARIOLA AND VACCINIA.

To the Editor of THE LANCET.

SIR—In a popular lecture on Vaccination, what view should be taken in reference to the experiments of Ceely, Badcock, and Thiele? The writer of a lately published pamphlet says, p. 16, "The small-pox of man conveyed to the cow produces cow-pox, but the cow-pox thus induced, retransferred to man, is as incapable as the natural cow-pox itself of producing infectious small-pox."

Is this view scientifically correct? The Lyons Commissioner, Dr. Warlomont, Mr. Fleming, and others assert that small-pox and cow-pox are distinct diseases. Fleming is very positive on this point (Human and Animal Variola). He states that human small-pox is not vaccinia, and cannot be converted into that malady; and that all recent attempts to produce this conversion in France, England, and Italy have failed.

Warlomont writes (June 28th, 1881), "L'enquête lyonnaise a donné le dernier coup à l'idée représentée par MM. Ceely, Badcock, Burrows, et Thiele, laquelle enseignait que la variole de l'homme confiné par inoculation à la vache est restituée par celle-ci à l'état de vaccin. *Cela est faux.* . . . Il existe deux maladies distinctes."

I wish to give the real truth about vaccination, and ask—which is truth?

I am, Sir, yours truly,

INQUIRER.

December 11th, 1882.

. There is not sufficient definite knowledge on the subject to enable us to answer the question positively, but we are disposed to think the former view more likely to be correct. Natural cow-pox is essentially a disease of the female animal, the site of the eruption being the udder. This raises the presumption that the disease is produced by inoculation, seeing that it is with the female animal, and particularly with this part, that man comes in contact in the process of milking. The fact that since small-pox has become far less frequent than formerly in rural districts, so called natural cow-pox has almost disappeared, tends to confirm this view, and makes it probable that the latter disease was dependent on the former. The more recent failures to inoculate the cow with small-pox are likely enough to be due to the same kind of difficulties as those which at one time led attempts to cultivate cow-pox in successive calves to be attended by failure. The Lyons experiments cannot be regarded as conclusive.—ED. L.

CINCHONA BARK.

To the Editor of THE LANCET.

SIR—I shall be glad if you could, through your influential journal, assist the growers of cinchona bark in bringing their valuable tonic within the reach of the million at a price which will well content the producer, and not be exorbitant to the laboring poor.

The importance of this new branch of Indian and Ceylon industry is remarkable, and their fine cinchonas, rich in sulphate of quinine, are driving the corky barks of South America before them. But, although the price obtained in London at wholesale auctions does allow a splendid profit to the manufacturer who converts the bark into sulphate of quinine, yet a further immense profit is made by the retail chemist, who purchases it at 7s. or 8s. per ounce of 437 grains, and retails it at 300 per cent. profit on 480 grains to the ounce. And this magnificent tonic, so prized by physicians on account of the certainty of its effects, cannot be prescribed by doctors in the quantities they would wish to a poor man or his wife and children, owing to the exorbitant rates charged by chemists (especially country chemists) in making up a prescription, so that practically it is only the moderately wealthy to whom the doctor gives a quinine prescription without stint.

In one of the largest cities of the north I lately purchased a packet of quinine powders, being charged 1s. 9d. for thirty-six grains, or at the rate of 23s. per ounce; and the druggist seemed surprised at my remarks at the price. If this is the price at our town establishments, what must it be in country towns and villages? And in the interest of the masses of the people and the hard-working planter I would solicit your aid.

I am, Sir, yours faithfully,

THOMAS DICKSON, Managing Director.

The Scottish Trust and Loan Company of Ceylon (Limited),
Palmerston-buildings, London, Dec. 21st, 1882.

"SALICYLATE OF SODA IN SCARLATINA."

To the Editor of THE LANCET.

SIR—I wish to state that for several months past I have prescribed the following mixture in cases of scarlatina, and with the happiest of results:—

Forty grains of salicylic acid, half a drachm of carbonate of ammonia, two drachms of syrup of mulberry, and three drachms of syrup of lemons to three ounces of water; one teaspoonful every two hours (for a girl eight years of age), the dose to be regulated according to age and sex.

The subject is at present engaging my attention, and I hope on a future occasion to offer a communication on the subject.

I am, Sir, yours, etc.

P. W. M.

December 20th, 1882.

To the Editor of THE LANCET.

SIR—An extensive experience with the above has satisfied me that it is a very valuable medicine if used early and with sufficient power. It seems to modify the throat and nasal symptoms. The dose had better be left to the judgment of the practitioner.

I am, Sir, yours, faithfully,

JAMES COULDREY.

Scunthorpe, Brigg, Dec. 26th, 1882.

To the Editor of THE LANCET.

SIR—I have tried salicylate of soda in persons suffering from scarlatina, and have fancied it did good. I have also given it to all persons in communication with the patient, and to those in the house unprotected by previous attacks, and have, as yet, always appeared to prevent the disease spreading. I have tried it thus, fifteen grains every four hours, in three different families, the first of which was the most striking example. It was in the family of a fishmonger, where the parents and four children slept in two adjoining rooms. One of the children was attacked by scarlatina, and in less than a week a second took it. There was no possibility of absolute isolation, but I put the other two children on comparative doses of salicylate of soda, whilst the parents took none, having previously had scarlatina. Both parents and one child had sore-throats for two or three days, but the other child never appeared to suffer in any way. This and other instances may be cases of *post hoc ergo propter hoc*, but made some impression upon the patients friends, and may interest some of your readers.

I am, Sir, yours, etc.,

AMAND ROUTH, M.D.

Clinical Remarks

ON A

CASE OF BRONCHIECTASIS TREATED BY TAPPING.

By C. THEODORE WILLIAMS, M.A., M.D., etc.

Physician to the Hospital for Consumption and Diseases of the
Chest, Brompton.

GENTLEMEN—Bronchiectasis in its worst form is one of the most troublesome affections the physician has to deal with, and the subjoined is instructive as indicating some of the difficulties.

Charles R—, aged forty, a baker, was admitted into Brompton Hospital on April 28th, 1882, under my care, with the following history. There was no consumption in the family; he was chilled twelve months ago, and had cough and expectoration ever since, with some pain in the chest and tightness, for which he became an inmate of the Bath United Hospital, and remained so till April, 1882. During this period he had night-sweats and more or less pyrexia, the temperature rising to 103° F., but being generally from 99° to 100° in the mornings, and 100° to 101° in the evenings.

On admission the cough was very harassing, inducing vomiting; expectoration abundant, purulent, and so fetid that the patient had to be isolated from the other patients. It contained no lung-tissue. Breath very foul. Pulse 106; temperature 99.4°; respiration somewhat hurried; weight eight stone four pounds and a half. Physical signs: Right side anteriorly hyper-resonant to upper border of the fourth rib; below marked dullness, and intercostal spaces retract on inspiration; bronchophony audible over the whole front, also coarse crepitation, replaced in certain spots by gurgle and cavernous breathing, these spots being situated in the second and third intercostal spaces, near the shoulder, and in the fourth and fifth interspaces between the nipple and shoulder. In the latter position the gurgle was audible over a spot of two inches diameter. Posteriorly, marked resonance from above to the angle of the scapula, below which was dullness with retracting intercostal spaces, as in front; crepitation audible over the whole surface, with spots of gurgling and cavernous sounds between the ninth and tenth

ribs, immediately below the lower angle of the scapula, and again in another spot at the same level, two inches nearer the spine. Left side: Crepitation with wheezing sound heard over the lower half of the posterior surface. The diagnosis was chronic pneumonia of both lungs, accompanied in the case of the right by extensive bronchiectasis and adhesion of pleura. The fetor of breath and expectoration were treated by the patient wearing a Roberts' respirator containing a mixture of creasote and carbolic acid, the air of the ward was diffused with vapor of thymol or eucalyptol, the expectoration was duly deodorized by terebene, and stimulant expectorants administered, in addition to two ounces of brandy daily. Notwithstanding these measures, the cough continued sufficiently violent to cause vomiting, the expectoration was so fetid as to greatly distress the patient, and, in spite of all precautions, the smell reached the gallery and penetrated into some of the adjacent wards. After consultation with Drs. Douglas Powell and Tatham, I decided to ask Professor Marshall to make an opening into the largest bronchiectasis, and thus to secure efficient drainage.

On May 22nd Mr. Marshall made a vertical incision along a line drawn by myself, from the fourth to the sixth ribs, about two inches to the right of the right nipple. He divided the skin and laid bare two intercostal spaces, the object being to puncture the upper space, and in case of our thus failing to reach the bronchus to try the lower space without a fresh incision. Mr. Marshall then plunged a special trocar and cannula, with director attached, to the depth of four inches towards the root of the lung. Air hissed through the opening, followed by a large quantity of fetid matter, which was ejected with considerable force. Mr. Marshall then extended the opening by means of his knife and finger, and more fetid mucus, this time mixed with sloughs and shreddy lymph, appeared; some blood also flowed. A piece of French catheter-tubing was fastened in, through which the discharge passed into antiseptic dressings.—23rd: Slept well; a fair amount of discharge runs through the tube; expectoration diminished, hardly fetid; wound looks well. Temperature 99.8°; pulse 100.—24th: Dr. Hicks found the tube to be slightly movable; discharge free and not offensive; expectoration thirteen ounces, devoid of smell, and breath tolerably pure. Two days later, the expectoration and discharge remaining about the same, the patient had diarrhoea, lasting two days,

arising, it was supposed, from swallowing sputum; urine 1020, no albumen.

June 1st: The tube was changed, and the patient was allowed to walk in the grounds of the hospital. He remained fairly well; the expectoration about seven ounces daily, and the discharge tolerably sweet, till June 8th, when the discharge increased; there was a slight rise of temperature to 100°.—4th: The patient complained of headache.—12th: The sputum slightly fetid. Still headache. Discharge increased.—17th: Patient has had severe frontal headache and vomiting with much flatus since 4 A.M. Wound the same; discharge more fetid. Temperature 101.6°. Ordered a calomel and podophyllin purge. This produced a number of motions, but no relief to the headache, which increased, and appeared to correspond with a diminution of the sputum, the quantity falling from six ounces to one ounce and a half on the 20th, and on the 24th he became drowsy, with more headache. Movement was impaired on the left side. No expectoration.—26th: Headache diminished; left pupil large. Breath very offensive. No sputum.—29th: Very drowsy. Passes motions under him. Wound the same.

July 1st: Complete hemiplegia of the left side of the body. The patient was drowsy and nearly unconscious. He died five days later, the sputum being altogether retained. The autopsy was performed on the following day. The subjoined is an abstract of Dr. Ewart's, the pathologist, and Mr. H. Williams', my clinical assistant, notes. A fistulous opening was seen in the right side of the chest between the fourth and fifth ribs, two inches to the right of the nipple line. The right pleura was universally adherent, rather closely so, by means of a strong fibrous tissue. The right lung was deeply congested and practically devoid of air; the tissue was collapsed, sodden, congested, and infiltrated with pus. A more or less uniform dilatation of all the small bronchi was noticeable on close inspection. Sacular dilatations as large as peas or almonds existed in the thickness of the basic fringe from sternum to vertebrae, but the main disease was situated in the lower part of the upper lobe anteriorly; and in the anterior portion of the lower lobe. The greater part of the sternal portion of the upper lobe was converted into a baggy multilocular sacculatation with thin but very tough fibrous walls, and containing some fetid fluid. This cavity, which was typically bronchiectatic, was also of the size of an orange, and communicated by an artificial channel with the fistulous opening on the chest wall, showing that the principal dilatation had been successfully tapped. In the sternal portion of the lower lobe the sacculations were much smaller, but very numerous and separated by a tissue thoroughly soaked in purulent fluid. The posterior parts of the lung were comparatively free from disease with the exception of two inches and a half above the diaphragm in the interscapular region, where a series of small sacculations about the size of a walnut was found. The left lung had no pleural adhesions, and was crepitant throughout, and tolerably healthy. No bronchiectasies were detected in it. The bronchial glands beneath the bifurcation of the trachea were enlarged, pigmented, and soft. No tubercular or caseous deposits were found in either lung. The brain weighed fifty-five ounces, and in the right hemisphere was discovered a cyst as large as a Tangerine orange with walls varying in thickness from one-eighth to one-sixth of an inch containing pus. No abscesses were discovered in the other organs, which were carefully examined and found quite normal.

This case exemplifies some of the difficulties we have to encounter in the treatment of bronchiectasis.

The diagnosis was based on the position of the physical signs, especially of the spots of gurgle, which are generally peculiar to bronchiectasis, and on the character of the expectoration; and it has been proved by the autopsy to have been fairly correct. It must be admitted that much aid was derived from the fact of the cavernous sounds being very localized and apparently superficial. We had not to deal with a labyrinthine series of dilatations, as in a case communicated by me to the Clinical Society in 1879, where cavernous sounds were audible over a far larger surface than the size of the cavity, owing to its peculiar form. The entire failure of antiseptic inhalations, the knowledge of an adherent pleura, and the certainty of speedy death from septicæmia, induced me to have recourse to the operation, with the immediate results of which I was quite satisfied. I would specially draw attention to the advantage of making an incision, as Mr. Marshall did, over two intercostal spaces in cases where the area of gurgle extends as far; so that, if puncture in the first space fails, we can try the one below or above, as the case may be, without fresh incisions. Another point is using Dr. Hicks' admirable combination of trocar, cannula, and director,* so that the channel into the cavity may not be lost through accident—a by no means infrequent occurrence—but gradually enlarged with the knife, and a large drainage-tube introduced. The wonderful improvement in the cough, the diminution of the expectoration, and disappearance of fetor, indicated in this case, as in Dr. Douglas Powell's case recorded in the 63rd volume of the *Medico-Chirurgical Transactions*, that much of the expectoration was due to the irritation set up in the bronchi by the passage of fetid secretion; and the marked amelioration made us hope that we were getting over our difficulties. But the return of fetor, the diminution of the expectoration, and, lastly, the pain in the head, followed by hemiplegia, showed clearly that absorption of matter and pyæmia had set in. The presence of an abscess in the brain and the total absence of any other abscesses in other organs were remarkable, and made one doubt at first if the brain abscess were pyæmic, but the curious relation between the diminution of expectoration and the increase of pain in the head certainly pointed to a pyæmic origin. The expediency of operating at all in these cases must be judged of by considering their probable termination. Some patients appear to gain expectorating power by using antiseptic expectorants in the form of medicines as inhalations, and are enabled to empty their bronchi sufficiently to prevent large and fetid accumulations. In others one of four events happens: (1) Either some of the fetid secretion passes during the movements of respiration into adjoining bronchi, or into the main bronchus of the opposite lung, and gives rise to septic pneumonia and death; (2) or the fetid products are absorbed by the lymphatics and bloodvessels, and give rise to pyæmic abscesses in some part of the body, as in the present case; (3) or, again, the bronchiectasis may burst into the pleura and cause pneumothorax; (4) or, lastly, the patient may die of suffocative bronchitis from the secretion penetrating into all or the greater part of the alveoli. All these four terminations are fatal in a shorter or longer period, and it is to obviate them that operations are undertaken. Taking the forms of bronchiectasis into account, of the two cylindrical and globular, the globular form of dilatation of the bronchi is the worst to treat, because all tonicity of the walls appears to have been entirely lost, and although we may tap and relieve one of

* Lately exhibited at the Medical Society of London.

these collections of fetid pus, we never can be quite sure that another one does not exist in another part of the lung, so that not one but many operations are required, and it looks sometimes as if there was more probability of our reaching the end of the patient's life than of the end of the operations. In the three other cases of bronchiectasis on which I have had operations performed, in all more than one operation was performed. In one six openings, in another three, were made, and this last patient stood the operations well, and is still living, a year and a half after. In the present case we were fortunate enough to hit the largest of the bronchiectases, and I hoped, as it was the lowest, that it would carry out sufficient drainage of a large portion of the bronchial tree. The question may be asked why I did not have another operation performed, but we had no indications. The opening was not blocked, but patent, and the septic symptoms came on too rapidly to allow of more apertures being made.

Clinical Lecture.

ON

CALCULUS IN THE FEMALE BLADDER.

*Delivered in University College Hospital,
Oct. 23rd, 1882,*

By CHRISTOPHER HEATH, F.R.C.S.,
Holme Professor of Clinical Surgery.

GENTLEMEN—You saw me last week remove from the bladder of a woman aged thirty-three the mass of calculous material which I show you in this bottle, and which weighs, now that it is dry, just one ounce. The patient is a married woman, and had been confined six weeks when she presented herself in the out-patient department, complaining of pain about the bladder and frequent micturition. For this she was sent upstairs to see me, and I had no difficulty in detecting a large mass of stone in the bladder. When placed upon the table in the lithotomy position, you saw that I proceeded to dilate the urethra with a pair of polypus forceps, and then introduced my little finger and subsequently my forefinger without difficulty. In this rapid dilatation there is of course some laceration, and it is usually upwards under the pubes, and does no harm. My finger enabled me to feel a very irregular mass of phosphatic stone, which I proceeded to break down with small lithotomy forceps, and I was able with these, with a scoop, and by washing out through a vulcanite speculum, to remove the debris which we have in the bottle. After clearing out all the fragments, I found that the bladder was in part encrusted with phosphates, and this mortar-like material I scraped away with the nail of the forefinger and a lithotomy scoop, until I was satisfied, by compressing the bladder with the other hand so as to sweep the finger over the whole interior of the viscus, that the mucous membrane was clear. Then, lastly, through the little vulcanite speculum, I applied a solution of nitrate of silver (a drachm to the ounce) over the whole surface of the interior of the bladder, and sent the patient to bed with a half-grain of morphia suppository in the rectum. I expected that there would have been more or less complete incontinence for a day or two, after which the patient would have recovered perfect control; but this was not the case. She was able to hold her water completely on the day of the operation, and passed from the first acid urine, instead of the

abominably offensive ammoniacal urine which had been present before. Now, this I find the invariable result of mopping out the bladder with a strong solution of nitrate of silver; and some of you may remember a man in whom the same thing was seen after lithotomy. The woman is now taking her food well, and is fairly convalescent, so much so that I have allowed her baby to be put to her breast again.

The symptoms of stone in the female closely resemble those in the male, except that, from the close propinquity of the bladder to the uterus they may be referred to the latter organ. Frequent micturition, pain especially after emptying the bladder, with "bearing down," should direct attention to the bladder and the condition of urine, which last is probably thick, and may occasionally contain blood. The detection of a stone with the sound is comparatively easy, for the urethra is short, and there is no prostate behind which a small stone can lie hid, whilst the ease with which the fundus of the bladder can be simultaneously examined with the finger in the vagina makes the diagnosis simple enough.

Calculus in the female may be of renal or vesical origin, or both, just as in the male; but there is the peculiarity about stone in the female that it may occasionally have for its nucleus some foreign body introduced by the patient herself. If the foreign body is small, such as a piece of cork, and is completely enveloped by the calculous matter, it in no way complicates the treatment; but cases are not very uncommon in which a hairpin or some other implement has been introduced into the bladder, and having escaped the patient's grasp, has been left there to form the nucleus of a concretion which is certain to form. In these cases the foreign body projects from the stone, and may not improbably have pierced the bladder, and given rise to serious complications.

Stone is not nearly so common in the female as in the male, the proportion between the two sexes being, according to Mr. Poland, one in the female to twenty or twenty-three in the male; and the same author remarks that "statistics respecting stone in the female, the operation and its consequences, and the mortality after operation, are incomplete and unsatisfactory." I am inclined to think, from what I have seen, that stone is more common in the female than is here stated, or than is generally supposed, because in all the cases I have had under my care the disease had not been recognized until shortly before I saw them, although the symptoms had long been present, and had been for the most part referred to uterine disorders. Irritability of the bladder is so common an accompaniment of uterine disease that it is easy to understand how both patient and doctor may be deceived by the symptoms produced by stone; but I would warn you, in all cases of uterine complaint, not to be satisfied without making both a rectal and a vesical examination if the symptoms are at all obscure or do not yield readily to appropriate treatment. When a vaginal examination is being made, it is so easy to pass the finger into the rectum and to slip the uterine sound (if no more convenient instrument is at hand) into the bladder, that there really is little excuse for overlooking disorders of any of the pelvic viscera.

The treatment of stone in the bladder of the female has been simplified almost as much as that of calculus in the male by the "one-sitting" method of lithotripsy introduced by Bigelow. In former years I should have hesitated to break up a stone weighing an ounce and have probably had recourse to vaginal lithotomy, of which I shall speak presently. Of course lithotripsy for small stones has been often performed in the female, and

I ventured some years ago thus to break up a small mulberry calculus, the fragments of which may be seen to be covered with phosphates. The ordinary lithotrite, or a shorter one made for the purpose, may be readily employed, or where, as in the great majority of cases, the stone is soft and friable, recourse may be had to simple lithotomy forceps and the crushing power of the hands. Bigelow's, Thompson's, or Clover's evacuator may be employed in the female as in the male, but I think I saved time in my case by using simply a vulcanite urethral speculum and washing out the fragments with an ordinary Higginson's syringe.

Extraction of small stones per urethram with polypus-forceps or a scoop is readily performed if the urethra is rapidly dilated in the way I have described; but it is never worth while to drag out large calculi at the risk of producing incontinence, when they can be so easily reduced in size by crushing. The method is, however, very satisfactory for the removal of the foreign bodies which occasionally find their way into the female bladder. Various ingenious instruments have been contrived for catching, doubling up, and extracting such articles as hairpins; but I have found practically that with the finger introduced through the urethra there is no difficulty in guiding a pair of polypus-forceps, and extracting a hairpin or other similar body without the risk inseparable from a supra-pubic lithotomy, which has been performed in similar cases.

The operation of lithotomy in the female resolves itself into a very simple proceeding—viz., cutting through the vaginal and vesical walls where they are in contact, and is hence called vaginal lithotomy. Let me remind you that the peritoneum does not touch the anterior wall of the vagina, which may therefore be divided quite up to the os uteri without risk to that membrane, whereas the pouch of Douglas lies between the upper part of the posterior vaginal wall and the rectum, and is liable to injury by obstetric instruments, etc. Vaginal lithotomy is no new operation, for it has been long known to surgeons, but the great modern improvement in it is the practice of closing the wound immediately by wire sutures so as to obviate the formation of a vesico-vaginal fistula. I show you three large stones which I removed from different women by this proceeding some years back. The first stone weighs one ounce and a half, and is remarkable, as you may see in the section, for having consisted originally of three angular calculi, which had become fused together in a mass of carbonate and phosphate of lime, measuring 2 inches by $1\frac{1}{2}$, and being 1 inch thick. This I extracted from a woman aged forty-nine, in whose bladder I detected a very distinct pouch, in which no doubt the stone had originally lain. I closed the wound with tin wire sutures introduced through the whole thickness of the bladder and vagina, and the patient made a perfect recovery. The second stone is nearly circular in shape, its long diameter being $2\frac{1}{4}$ in. and its short diameter $2\frac{3}{4}$ in., and its greatest thickness $1\frac{1}{2}$ in. It weighed two ounces, and I extracted it from a woman aged forty who had long suffered from pain supposed to be uterine. In this case the closure of the wound was not entirely successful, and she had slight incontinence when in the upright position, but declined further interference. The third stone consists of one large mass and a quantity of débris, weighing altogether three ounces and a half, which I extracted from a woman aged fifty, who made a perfect recovery.

You will thus see that there is no difficulty in extracting very large calculi from the female bladder entire, but it is in some sense a reproach to

our art that stones should be allowed to attain such a size. Early detection is as desirable in the female as in the male, and the great majority of such cases can be best treated by lithotripsy at one sitting.

Clinical Remarks

ON

BILATERAL FACIAL PALSY.

By J. S. BRISTOWE, M.D., F.R.S.,

Senior Physician to St. Thomas's Hospital.

BETWEEN three and four years ago I was consulted in a case of injury to the head; attended, or rather perhaps followed, by symptoms which interested me a good deal at that time.

A young man, twenty-one years of age, was alighting one morning (five months previous to the date of my interview with him) from a train which had overshot the Deptford station on the London and Greenwich line, when, mistaking in the dark the low wall which flanks the railway for the platform, he stepped on to it, and the next moment was precipitated head-over-heels into the road beneath. The main facts which I learnt concerning his subsequent history were as follows: that he was carried insensible to the *Dreadnought* Hospital, where no local signs of injury to the head were detected beyond the fact that blood was oozing from the ears and nose, and where also some of the ribs on the left side were ascertained to be broken; that he remained absolutely unconscious for about four-and-twenty hours, and partly unconscious for two days more; that during this time it was observed that he was paralyzed on the left side of the body and on both sides of the face, that he squinted and was deaf, and that owing to a wound of the lung pneumothorax was developed on the corresponding side; that after his recovery of consciousness he remained feeble in mind, with impaired memory and tendency to delirium and emotional disturbance; but that (with the exception that the squint disappeared from the eye first affected and then attacked the other) gradual improvement had taken place, chiefly in his general health and the condition of his chest, but to some extent also as regards his cerebral symptoms.

He was a spare but well-nourished man, with a curiously vacant expression of countenance. He had almost complete paralysis of both seventh nerves. His face was smooth and void of wrinkles. He could not close his eyes, or whistle or blow out a candle, or retain fluids in the anterior part of the mouth, or bring his lips into actual contact. Neither could he pronounce the labial letters *b*, *p*, *m*, *v*, *f*, or *w*; but he could pronounce all others, and in conversation invariably replaced the labials by their corresponding linguals—*b* by *d*, *p* by *t*, *m* by *n*, and *v* and *f* by *th*. His hearing was impaired on both sides, more especially on the right; but he could hear. The external rectus of the left eye was paralyzed, so that he presented an internal squint. The left upper extremity was partially paralyzed, a little contracted, and slightly but generally wasted. Moreover, there was slight impairment of sensation, especially in the little and ring fingers. The left leg also appeared a little wasted, but he seemed to use it almost as well as the other. He was, so far as I could judge, quite sensible; but it was said that his memory was still defective, that he was incapable of application, and that now and then he would give way to anger, which formerly he never did. No other abnormal phenomena referable to the nervous sys-

tem were observable. His sight was good, he could distinguish colors, his pupils were equal and acted naturally, and there was no paralytic condition of any of the cerebral nerves but those which have been specified. There was impaired immobility of the left side of the chest, with some contraction of it, displacement of the heart to the left, and dulness at the base. No signs, however, of progressive disease were detected.

There was no evidence as to what part of the head was struck in this case, or indeed that the head itself received any direct injury. But it was quite clear that damage had been inflicted on the soft parts within the skull. There was doubtless some bruising of the brain; but where exactly it was, under the circumstances, it is idle to speculate. So much, however, was clear—namely, that some bruising or laceration had occurred in the neighborhood of the pons Varolii, and that there had been more or less implication of both acoustic and both facial nerves and of the sixth nerve on the right side. And the opinion I formed was to the effect that he had had a fracture of the base of the skull; that the several nerves above named had been damaged, either by being themselves bruised or by being pressed upon by blood extravasated beneath the dura mater; and that the hemiplegia might have resulted from damage to the motor tract in the immediate vicinity. The probability that he had fracture of the base was enhanced by the bleeding that took place from both ears at the time of the accident. I may here state that I have recently learnt from Dr. Kavanagh, under whose care the patient was, and who still sees him from time to time, that he has so far recovered as to be able to earn a livelihood, but that his paralytic symptoms and his peculiarities of speech remain much as they were.

I was chiefly interested in this case because of the existence of double facial paralysis—a condition which is very rare, and which I have seldom seen—and of the association with it of a phenomenon which, on theoretical grounds, might be expected to be present in such cases, but which I had never hitherto observed—namely, absolute inability to utter any labial letter. I need scarcely say that in paralysis of the portio dura of one side defective articulation is not generally noticeable, and that the patient can pronounce the labials without difficulty. My interest in the case was revived about a year ago by the fact of another patient coming under my care, who (also as the consequence of injury to the head) suffered from double facial paralysis, but who presented additional symptoms of a remarkable character; and in whom the opportunity was afforded of investigating post mortem the causes of the phenomena observed during life. The following are the particulars of the case:—

A man, formerly a soldier, forty years of age, came under my care on Sept. 21st, 1881. Exactly two months previously he had fallen down some area steps, and struck the back of his head, and had been carried insensible to one of the London hospitals. A deep cut was found in the occipital region, but no sign of fracture was detected, and he remained more or less insensible for a fortnight. At the end of a month he left the hospital presumably well. But I have since learnt that indications of paralysis of the facial nerves had been observed. During the ensuing month he remained at home, and it was noticed that he was much more irritable and fidgety than he had previously been, that he was inclined to be drowsy, and that his speech was thick and indistinct. Moreover, his appetite failed, he had a constant and painful desire to go to stool, the bowels being relieved with difficulty two or three times a day of a few small

hard scybala, and he lost flesh and strength. There was no impairment of memory, however, no vomiting, no loss of control over his bladder. On admission into St. Thomas's Hospital it was noted that he was a short, feeble, emaciated man, very bald, with sunken eyes, and an immobile, melancholy-looking face. There was a recent scar about two inches long in the occipital region. On closer investigation it was discovered that he had imperfect paralysis of both facial nerves; his forehead was smooth, he could not close his eyes, the nasolabial furrows were ill-defined, and if he attempted to laugh only a very slight movement was discoverable in the lower part of the cheeks and about the mouth. He could, however, close his lips, and had no difficulty in keeping fluids in his mouth. His want of variability of expression was clearly due to the paresis of his facial muscles, and the prevalent melancholy look was dependent partly on the same cause, but partly on the subsidence of the eyes into their sockets. There was no other obvious nervous default in connection with the head and neck. The muscles of the eyeballs acted properly, the pupils were equal, and acted to light and accommodation, his sight was good, and the fundus of the eyes showed no pathological change. There was a little deafness on both sides, but this was said to be of old date. His tongue was protruded straight and without difficulty; there was no defect of mastication or deglutition, and pronation remained unaffected. His speech, however, was, as it had been said to be, thick and indistinct. He could enunciate all the individual labial sounds, and even the linguals, but when uttering them in combination they were imperfectly articulated and slurred. His speech, in fact, was exactly such as is observed in cases of early glosso-labio-laryngeal palsy. It is right to say, however, that he always asserted that his speech was naturally indistinct, and that he did not admit it had deteriorated lately. The arms, especially the forearms, were much shrunk; the legs also were extremely thin. There was no wasting or paralysis of particular muscles or group of muscles; there were no tremors; but there was extreme general muscular debility. Sensation was unimpaired; the superficial reflexes were little marked; the tendon reflexes were present, but perhaps a little sluggish. He appeared to be low-spirited and apathetic, and complained of pain at the back of the head, and in the umbilical and epigastric regions. The chest expanded imperfectly, but all the thoracic viscera appeared to be healthy. The respirations were normal as to frequency, and the pulse feeble, but otherwise natural. The abdomen was shrunken and its walls flaccid; no tenderness or tumour could be detected. Tongue thickly coated, appetite bad, no sickness; he complained of persistent uneasiness about the rectum, and a constant desire to defecate, but there was no evidence of piles or other disease in the rectum or anus; there were not, and there had never been any discharge of pus or mucus, and the motions, which were passed with extreme difficulty and much straining, were voided only occasionally and in small quantities; they were healthy in character. The urine was normal in amount, slightly alkaline, and containing amorphous phosphates, but no albumen or sugar; its specific gravity was 1025. His temperature was normal; his weight eight stones and half a pound.

There was no very great change in the patient's symptoms during the remainder of his illness, excepting that he gradually became thinner and weaker, and more apathetic.

He was always quiet, reserved, and disinclined to speak; for the most part indifferent as to what was going on around him, yet sometimes becoming irritable and worried about trivial things. His ap-

petite was bad, but he complained neither of sickness nor of thirst; and his bowels continued almost to the end to be a source of great discomfort and misery to him. There was never discovered any sign of local mischief, and the motions were always normal in character, or perhaps a little hard; but he suffered from almost constant tenesmus, which was only momentarily relieved by the occasional passage of small lumps of fecal matter. It may be added that there was no discernible undue accumulation of feces in the rectum, and that on the average a sufficient amount was passed daily. At times, and more especially latterly, this symptom was kept in abeyance by the use of morphia suppositories. His paralytic symptoms remained without change. His temperature was generally about the normal, occasionally rising a little above, but more commonly falling a little below. He had at all times a great inclination to remain in bed; and for the last three or four weeks of his life remained in bed almost constantly, lying huddled up on his side, with his head buried beneath the bedclothes, and though quite sensible, or at any rate understanding all that was said to him, seldom vouchsafing any answer to those who questioned him. He seemed also to be getting more and more imbecile. About a week before his death his weight was ascertained to be only 6 st. 4 lb., so that he had lost nearly two stones from the time he was received into the hospital. During the last week of his life he vomited occasionally.

About noon on Dec. 23rd, two months after admission, he was discovered insensible, with head thrown back, and mouth open, sweating profusely, breathing at the rate of four respirations in the minute; his pulse very feeble, irregular, and about 90; his pupils contracted and equal; and his temperature 96° 7". He continued in this state (his temperature, however, falling to 95°) until his death, which took place shortly before five the same evening.

The points of particular interest in this case were; the presence of double facial palsy; the curious combination of irritability, apathy, and drowsiness, and apparently progressive enfeeblement of mind; the rapid general wasting of the tissues, and more especially of the muscles without paralysis; and the constant and painful desire to defecate, apart from the presence of any local conditions to explain it. To what were these symptoms attributable? That there was damage to the soft parts within the skull was certain; and that there was fracture of the base of the skull was probable, at least I thought so. It is true that no fracture was detected at the time of the accident, that there had been no bleeding or discharge of watery fluid from the ears, and that a blow on the back of the head is less likely to be attended with fracture at the base than blows in several other situations. But, on the other hand, a blow here not infrequently causes a linear fracture of the occipital bone which fails to be recognized during life; and such a fracture might easily run up to the suture between the occipital and temporal bones, and might lead to the separation of the edges of these bones, and then become connected with a fissure running across the base of the skull. Besides which we had in this case just that kind of paralysis which might be expected to result from a basal fracture, which seemed best explained by such an accident, and which in the case first narrated was almost certainly due to that cause.

One can never predict with certainty either the amount or the situation of the injuries which after death will be found to have been inflicted on the brain even by accidents in which the bones of

the skull are unbroken. Not unfrequently there is injury of the part corresponding to the blow; sometimes there is laceration either in the substance of the brain or of some of the delicate laminae or processes which extend between adjoining parts; almost always there is more or less serious bruising by contrecoup of those regions of the surface of the brain which abut on bone opposite to the seat of injury. On the whole, however, considering that the patient had not fallen very far, and that there was no depression of skull at the point which had been struck, I was inclined to think the chief, if not the sole, injury to the brain was from contrecoup. I shall best explain my views, perhaps, by narrating a case that occurred to me some years ago.

A man, walking over London-bridge, was seen by a policeman to stagger and fall violently on the back of his head. He had probably slipped on a piece of orange-peel. He was picked up insensible, and brought to St. Thomas's Hospital, where in a very short time he died. There was some bruising and laceration of the integument over the occiput; but no fracture was discovered. At the post-mortem examination, however, a linear fracture of the occipital bone was found, extending from an inch above the tuberosity into the foramen magnum, and situated to the left of the median line. There was much effusion of blood into the cavity of the arachnoid and into the subarachnoid tissue; and there was considerable bruising, with laceration, of the anterior portions of each cerebral hemisphere, and of those portions of the middle cerebral lobes which were in relation with the greater sphenoidal wings. There was no other injury.

Now in this case there was just such a fracture as I supposed might have occurred in the case under consideration, but its direction was somewhat different; and the mischief within the skull, excepting that there was no damage to the facial nerves, was precisely that which usually results from contrecoup, and which I expected to find on the present occasion. I hoped, however, to find something more.

A careful autopsy was made, at which I was present. The scar on the occiput was very distinct; but there was no further affection of the soft parts outside the skull. There was no trace of injury to the skull itself; clearly there had been no fracture of the base. The front and under part of each anterior cerebral hemisphere were softened and of a yellow-ochre tint. The same conditions were observed in the anterior and under part of each middle lobe; and a few yellowish spots were observed about the flocculi and neighboring part of the cerebellum. In the first two situations the softening and discoloration involved the whole thickness of the grey matter; but the subjacent white matter appeared to be unaffected. In the last situation the change was extremely slight and wholly superficial. Indeed, it seemed probable that the brain substance itself was not involved, and that the pigmentary deposit was limited to the pia mater. With these exceptions the brain was perfectly healthy; and there was no visible damage either to the seventh or to any other of the cerebral nerves. The medulla oblongata and the cord were healthy, and presented no traces of secondary degeneration. The thoracic and abdominal viscera, including the rectum, were sound.

The results (shall I confess it?) were somewhat disappointing to me. But it is by the cases that thus disappoint us that we learn, or are made to think. It is such cases too that ought especially to be stored up in the memory, in order that when other obscure or exceptional, or apparently mis-

leading, cases come under observation, they may serve to illustrate or explain them, or to correct the inferences we are disposed to draw from them. Now, although there was no fracture at the base of the skull, or visible injury to any of the cerebral nerves, it is not very difficult I think, to understand how some damage may, nevertheless, have been inflicted on the facial nerves within the skull sufficient to have induced the permanent but incomplete paralysis from which the patient suffered. The effects of contre Coup in this case were observable in all those parts of the surface of the brain, which were antipodean, so to speak, to the part of the skull struck; or, in other words, in those parts of the nervous centres which were in contact with the anterior bony boundaries of the anterior, middle, and posterior fossæ of the skull severally; and the portio dura is so situated within the skull as, perhaps, to be more amenable to damage under these circumstances than any other cerebral nerve. The failure to discover any pathological change does not, of course, prove that no damage had been sustained.

Further, I do not think it need be assumed from the conditions found in this case that the double facial palsy observed in the first case was not due to fracture across the base of the skull, though they prove clearly enough that a blow on the head may cause such paralysis apart from fracture. But the chief interest of the case, after all, lay elsewhere—namely, in the presence of the group of non-paralytic clinical phenomena, to which nothing similar existed in the first case, and in their explanation. What caused the patient's irritable apathy and apparent enfeeblement of mind? What caused his persistent mental misery? What caused his progressive and rapid emaciation and muscular enfeeblement? To these questions, I am sorry to say, I can give no satisfactory answer. All the perceptible damage to the surface of the brain was well removed from the generally recognized motor and sensory areas; a fact which goes to explain the absence of cerebral paralysis and of impairment of the special sensory functions. Cases have been adduced to show that disease of the front part of the anterior cerebral lobes involves a profound alteration of the moral character of the patient and enfeeblement of his intellect.

On the other hand, many cases of injury of this part have been met with, in which no special symptoms of importance have ensued. "Dr. Crichton Brown, however," (I quote from Ross), "has drawn attention to the fact that during the early stage of general paralysis of the insane, when the convulsions of the frontal lobe are particularly apt to manifest degenerative changes, the characteristic symptoms consist of 'general restlessness and unsteadiness of mind, with impairment of attention, alternating with *apathy* and *drowsiness*.'" These symptoms are identical with some of the special symptoms presented by my own patient; and on the whole, perhaps, are such as in the present state of our knowledge might be thought likely to follow on such lesions as were found. The gradual wasting and debility, and the rectal trouble, however, seem to me at present inexplicable.

I may add that in the tenth volume of the *Pathological Transactions* I recorded a case pathologically identical with this; but in which the only history obtainable was that the man had been earning his livelihood subsequent to the accident (of which there was no record) which caused the superficial cerebral hæmorrhage; and that after a bout of drinking he was attacked with epileptiform convulsions, of which he died.

THE
"Bradshawe" Lecture
 ON
SOME RARE AND NEW DISEASES.

*Delivered at the Royal College of Surgeons of England
 on December 13th, 1882,*

By SIR JAMES PAGET, F.R.S.

MR. PRESIDENT AND GENTLEMEN—It is my first duty, in delivering the first Bradshawe Lecture in our College, to offer a tribute of respectful thanks to the generous lady by whom it was founded, the widow of Mr. William Wood Bradshawe, a Fellow of this College, who practiced at Andover and at Reading, and died in 1866. He was a home-loving and studious man, who diligently cultivated his mind in both literature and science, and his widow, who survived him fourteen years, being desirous to testify her gratitude for the happiness which she owed to him, bequeathed a thousand pounds to this College, and as much to the Royal College of Physicians, on the condition that each should institute a lecture, to be given annually and to bear his name. She desired that the lecture should be on some subject connected with medicine or surgery, and that the choice of the lecturer should rest with the President of each College for the time being. She made no stringent regulations, and seems to have wished only to maintain her husband's name in good repute by associating it with the advancement of the science which he loved.

In my endeavor to fulfil her exemplary wish, I have chosen the subject of Some Rare and New Diseases. I hope to be able, in speaking of them, to illustrate a part of the natural history of disease which I think is too little studied—that part, namely, which relates to the variations and the combinations of diseases in hereditary transmission. Besides, both in the choice of its subject and in the whole enterprise of giving this lecture, I have looked for an opportunity of promoting pathology by promoting pathological museums, a motive which I am sure will be pardoned, though I am conscious of its being in some measure personal, for I have spent so much time and thought in museums, that I feel as if, in their greater utility, I should myself become more useful.

Now, first, respecting rare diseases, there may seem no want of opportunities of studying them. Our journals and the proceedings of our societies are full of the records of rare cases; many collections of such cases have been published, and there are many rare specimens in every museum. All these have that kind of attraction which belongs to everything that excites our wonder, but we too seldom let the wonder have its proper consequence; we too seldom let it provoke our curiosity so far as to make us search for the meaning and reason of the rarity. There is a question which we should often ask ourselves, Why is any disease rare? at least, why is any rare which does not depend on some accident or some rarely occurring external cause? I shall try to suggest answers which may be, in some instances, sufficient; but I fear that, in more instances, if I can be useful at all, it can only be by suggesting how answers may be found.

First, there is a difference, though it may often seem only a verbal one, between rare cases and rare diseases. A case may be called rare when, though it is evidently one of a common disease, it differs from the usual type or standard of that disease in some one or two features. Thus it is a

rare case when a common disease is found in an unusual place; as an epithelial cancer on the upper lip, or this fatty tumour on a finger; or in unusual quantity, as in this large cartilaginous tumour on a femur; or, again, a case may be rare in respect of the time of its occurrence. For instance, I have lately seen cancer of the rectum ending fatally in a lad of eighteen, and scrofulous abscess in a man of eighty; and many of us must have seen instances, though they are rare (and these are very important in the history of diseases), in which manifestations of syphilitic inheritance, usually evident in infancy, have not appeared till the time of youth or even of adult age; or cases may be very rare in respect of accidental complications or of the absence of some usual symptom. But of all these and other rare cases the number and variety are so great that it would be impossible to deal generally with them, except as with mere story-telling. It would be very useful if someone would collect hundreds or thousands of them, and arrange them, even though it were only under such headings as I have just indicated. But even as they are singly and in disorder, let me say that we ought not to set them aside with idle thoughts or idle words about "curiosities" or "chances." Not one of them is without a meaning; not one but might be the beginning of excellent knowledge, if only we could answer the question, Why is this rare? or, being rare, why did it in this instance happen?

But, because of their number and variety, I must pass by rare case and will speak only of some rare diseases—that is, of some diseases which are rarely seen and yet occur in a sufficient number of cases, and with sufficient uniformity, and sufficient difference from other diseases, to permit of their being described in general terms, and to justify their being called by distinctive names. And of these again, for they are numerous and various, I shall select only that group which seems most attractive; the group of those, namely, of which there seems reason enough for believing: First, that they were, lately, new diseases and have become more frequent; and, secondly, that they are due mainly to morbid conditions changing and combining in transmission from parents to offspring. I say due mainly. It is certain that changes in the external conditions of our life have influence on even those morbid conditions which are most personal; but this influence is very hard or impossible to trace in the cases which I have in mind, and it may to-day be neglected though not forgotten. For, in all these cases, the personal factors and those of which alone I have to speak are more potent than the conditional, the inner than the outer. We call these diseases constitutional, diathetic, or by similar names; but the chief fact in them is that they, or the necessary previous states or predispositions to them, are in-born and inbred.

Let me first show that there is reason enough for believing that some rare diseases of this kind were recently—say within the last century—new; and that more recently, though still rare, they have become more frequent. There is, I know, a general unwillingness among pathologists to admit that there are new diseases of this kind; and this unwillingness is often just, for many diseases that may seem new have probably existed long and been overlooked; they may be new to knowledge, but not new in fact. Bright's disease and Addison's disease were new in the sense of having first been well observed and described by those whose names they bear; but no one would venture to say of diseases so difficult to detect, as these used to be, that they did not exist long before they were well observed. We could as well believe that em-

bolism never occurred till just before it was found out, or that right-side hemiplegia used not to be associated with aphasia. These things were old before they seemed to be new; but how long they had existed neither records nor museums can tell. It would be, indeed, very interesting if we could tell the time and manner of first appearing in the case of many diseases which are now common; but it is scarcely ever possible. And yet, if you will allow me a digression, let me show what in some instances museums may supply, and what I hope they will in the future supply much more largely. Here are specimens of typhoid ulcers of the intestines preserved by Hunter. Few things have been more important in the knowledge of fevers than the clear proofs of the distinction between typhus and typhoid given by Sir William Jenner in 1850. It was one of the best life-saving discoveries of this century; before it both diseases were at least partially misunderstood, and neither was so well treated as now. Since the distinction between them was discovered it has been possible to trace in old recorded cases probable instances of both; but there is nowhere so clear evidence of the occurrence of typhoid a century or more ago as is given in these specimens of Hunter's preserved without name or history; not unobserved, and yet not in any fair sense understood. Now in this, as in many things, Hunter set us a good example. He did not think those things unimportant which he did not understand. He was a thorough naturalist, and kept specimens of everything in his field of study which, though not yet, might become useful.

But, however much of what seems to be new we may justly ascribe to our previous oversight of what was old, there yet seems to be evidence enough that new diseases are in progress of evolution, and that, as I have said, some of the rare diseases of which I have to speak are the earliest instances of the new. Good evidence of this kind is to be found, I believe, in the peculiar joint-disease discovered by M. Charcot in association with locomotor ataxy, and in the disease of bones to which I have given the name of osteitis deformans. Neither of these, I believe, was described till within the last few years. They may have been overlooked, but to believe this we must believe what is very improbable. We must believe that all the most acute and observant practitioners before our time overlooked, not merely obscure and transient diseases, difficult to study, but cases which lasted for many years and gave constant great distress, and were manifested in signs so plain that they could be recognized in the shape and gait, in the posture and whole aspect of the patients, in strangely large heads and curved limbs. And, further, we must believe that the morbid anatomists before ourselves overlooked changes of structure of the largest, most obvious, and most striking kind. It is, surely, very unlikely that they who studied and recorded such cases as those of extreme rickets and mollities ossium, and even called it rachitis adutorum, should have left unnoticed the cases of these two equally and somewhat similarly disfiguring and damaging diseases. This great improbability is strengthened by that which I believe to be a fact—that we have none but recently collected specimens of either of these diseases in our museums; not even among the crowds of bones and joints collected by our predecessors.

In twenty-six years I have seen twelve well-marked cases of the osteitis deformans, and about as many in which it was only partially evident. In the last six of these years I have seen seven of these cases, and others have been published, and yet I cannot find evidence that the disease was ever seen by any of those who had practice like

my own; Brodie and Stanley, who saw as many cases of diseased bones as any surgeons of the last generation, had seen no case but that which I showed them more than twenty-five years ago in the patient from whom these specimens were taken. Moreover, I cannot find an old specimen in our museums, or a representation of one in any book of plates, or a description of one in any catalogue. This might not seem very strange in the case of specimens troublesome or expensive to keep, or in such as are said to "show nothing." But these are very striking deviations from health, very plainly to be seen, and dry bones are neither costly nor troublesome to keep. We have large numbers of them collected by Hunter, Howship, Langstaff, Liston, Cooper, Stanley, and others, who collected not merely illustrations of diseases well known to them, but whatever was curious, whether it were understood or not. They would have looked on these bones as gems.

I might repeat this statement in nearly every particular concerning M. Charcot's disease. I believe there is not an old specimen in our museums. There is not one in the Musée Dupuytren; I cannot find a notice or an illustration of one. And yet this disease is now so far from being very rare that Dr. Buzzard has had nine cases under his eye at one time, and several have in recent years been shown in our societies.

Let me adduce one more instance of what I believe to have been new diseases within this century, though the museum evidence is not so strong as in those of which I have been speaking. Many believe, and, I think, quite rightly, that instances of typical gout, such as gained for it the name "podagra," have lately become comparatively rare, and that a large number of less acute diseases, regarded as forms of incomplete or suppressed gout, are much more frequent. It may be that some or many of these lesser forms were always as common as they are now, but were overlooked or were not distinguished from other similar ailments. But here is a specimen of the effects of phlebitis of the femoral and external iliac veins, which, with its history, may tell that gouty inflammation of the veins was, fifty years ago, if not a new disease, yet a much rarer one than it is now. Sir Henry Halford saw as much of gout, I suppose, as any man that ever lived; for he was for many years, during a very luxurious period, in the largest practice among the richest people in this town. He gave an account in 1832 of what he called phlegmasia dolens in the male. The disease so-called was common and well-known in women after parturition; so that, to justify his essay as a record of cases hitherto unobserved, it was enough for him to speak of phlegmasia dolens as occurring in men. He speaks of it as having been not long before regarded as "immediately occasioned by a deposit of milk;" but that "being tested by a more exact pathology," it was now attributed to "an inflammation of the veins of the pelvis." And he says, "he was much mistaken if he had not seen three instances of it" in men "within the last few years." He then relates the case of the nobleman from whom, several years afterwards, this specimen was taken by Sir Astley Cooper—an admirable example of phlebitis, which we may be nearly sure was gouty, showing the changes in the blood-clots and in the walls of the veins during many years.

At the present time, phlebitis of this kind in the male can scarcely be called a very rare disease. There are few, I imagine, in large practice who have not seen many more than three cases within the last few years. So, we may believe, I think, that the disease has become more frequent in the last fifty years; and may suspect that not long before Sir Henry Halford's time it may have been a

really new disease. It is hard to believe that it could have been overlooked. Its characters are strongly marked and evident to both eye and touch; it is a very painful, disabling, long enduring disease, often recurring, sometimes observed in several members of the same family, and commonly leaving the affected limb large, heavy, and clumsy for many years. Could this have been overlooked when similar limbs, in consequence of an allied, though not the same disease, were known and described in women, and while, as it happened, the subject of phlebitis, in its traumatic and pyæmic forms, was being very carefully studied? For there was a form of phlebitis much more common in the last century than in this; the phlebitis that occurred after bleeding. Hunter had studied this very carefully, had written on it, and shown it in these specimens; and after him, both this and the phlebitis after amputation were well known. Especially after the beginning of this century the phlebitis after amputation was thoroughly worked at. It was only three years before the publication of Sir Henry Halford's essay that Mr. Arnott's renowned paper on inflammation of the veins was published in the *Medico Chirurgical Transactions*. In the same volume are the chief papers by Dr. Robert Lee on phlegmasia dolens; and he describes cases of phlebitis associated with pelvic cancer; but not one spontaneous phlebitis is mentioned by either of them.

Now, I think that in all these facts there is enough, not, indeed, to prove, but to justify the belief that we have here examples of diseases which have appeared in this country for the first time within the last century, and which have since become sufficiently frequent, and acquired sufficiently constant and distinctive characters to be described in general terms and called by new names. Let me repeat; these are not diseases hard to be discerned. They are so well marked, so distressing, so long enduring, and both during life and after death so large and distinct in all their characters that it seems impossible that, unless they were very much rarer than they are now, they could have been overlooked.

I think it probable that there are other examples of the like kind; but I do not know them, and would rather go on to the second part of my subject—namely, to show the probability, or, at least, to justify the hypothesis, that these diseases are among the instances of the results of morbid conditions, changing and combining in transmission from parents to offspring.

It should hardly be necessary to argue that changes of type in inherited diseases—changes which may be compared with the variations of species or of varieties in natural history—do take place. Yet I venture to think that many of us are prone to think too little of these variations; to regard them as rather unmeaning exceptions, or as the results of some unusual external conditions diverting diseases from their customary course.

It will be better for us if we study, in pathology as in natural history, varieties as much as species; changes as well as more stable forms. Types of disease there are, standard forms, and the tenacity with which they are maintained—some, even, from pre-historic times—in all the varieties of the conditions of our lives is one of the most remarkable facts in all pathology. But they are not unalterable. Types vary in diseases, as in species; even in the diseases which depend least upon external conditions, and most on the qualities which are transmitted by inheritance.

Let me give some reasons why this must be.

1st. An exact likeness is never transmitted by inheritance; neither an exact likeness of either parent, nor an exact composite of both. This is

evident enough in features, size, weight, and all that we can observe in external things. If we could be exactly endoscopic we should observe equal variation within; the same want of exact likeness in liver and lung, and, I venture to say, in blood and lymph and plasma, and whatever goes to make up the whole person, healthy or diseased. The inheritance of likeness in disease, or liability to disease is, indeed, clear evidence of the transmission of likeness in the very minutest structure and composition. But the likeness is never perfect; it may in different persons deviate this way or that; it may vary towards disease or back again towards the healthy type; but it is never perfect, and in successive generations its degree of unlikeness may increase to a great width of difference.

2nd. The certainty and probable extent of this variation must seem the greater if we consider the mingling of diatheses, and of all dispositions and liabilities to diseases in transmission from and through both parents. Consider the difficulty of maintaining the "breed" in any of the varieties of the species domesticated or cultivated by us, in horses or dogs, in pigeons or in seedling plants; the care that both parents should be of the same blood, or the same race, and that their produce should be raised in all due conditions; and then consider how numerous, and wide, in spite of all this care, are the deflections from the type. With these facts before us we cannot imagine that diseased conditions should often be transmitted singly and unchanged; it is, surely, not likely that disease should be transmitted with more fixed conformity to type than normal compositions are. Hybrids and mongrels must be even more common among diseases than among species and varieties.

3rd. And, in thinking of the variation of diseases by combining or convergence of inherited qualities, we may not limit our thoughts to a single generation. It is reasonable to believe that instances occur of reversion, in which diseases or tendencies to disease may appear after a lapse of many generations. Such, I expect, are some of the cases in which leprosy has been seen, even of late years, in this country in persons never exposed to any of its external causes; and to the like of this we may refer, I think, some of the rare cases which defy all efforts to refer them to any combination of types of disease now prevalent.

Now, I half wish that I could escape from the necessity of testing my doctrine by my facts; but as I have often asked myself, so others may ask, how can the cases of rare diseases of which I have been speaking, be explained as the results of morbid conditions changing and combining in transmission from parents to offspring. In the phlebitis we may often trace a variation from the customary type or standard of the very old and heritable disease, gout. In many cases its relations to typical gout are clear. The patients are members of gouty families, and in many of them other signs of gout are evident, either coincidentally with the phlebitis or at other times; it has, in short, all the evidences of being one of the many forms of what is called "incomplete gout." But, for a reason why this variety of gout settles (if I may so speak) in veins, especially in those of the lower extremities, I can only guess at a convergence of inherited dispositions both to a modified form of gout, and to some condition of veins rendering them, among all the structures, the most sensitive to the gouty process. Certainly it is not accident which determines the disease to the veins, for this disease "runs in families." I know of its occurrence in two brothers and three of their cousins; and I have heard Sir Charles Locock tell of four sisters

who had phlegmasia dolens and whose father had crural phlebitis.

I am conscious that this is little more than guessing, and for the osteitis I must guess still further; or, rather, let me say that, to the furthest bounds of propriety, I must exercise that use of the imagination which may happily discern a way towards the truth. I imagine, then, that a likeness of the osteitis deformans to several other diseases may indicate a combination, in definite proportions, of transmitted dispositions to those diseases; a combination which has become possible by changes of the type of one or more of them. First, it shows some relationship to mollities ossium and rickets, for, though it is an inflammatory disease, which they are not, yet the softening which permits of the curving of the bones is distinctive, and hardly occurs in any other form of inflammation of bone in middle or later life. And, again, the relation of the osteitis to rickets and mollities ossium is notably indicated in the porous thickening of the skull, which is found in some instances of them all, and which is well marked in our specimens of genuine rickets from erroneous diet in young lions and young monkeys. Further, there appears some relation to gout, for some of the cases have known inheritance of gout, and instances are sometimes seen, in typically gouty persons, of a single bone having all the characters of the osteitis, though all the other bones appear healthy. Such a one is this femur, for the opportunity of showing which I am indebted to Mr. Bowly of St. Bartholomew's. There is a likeness, also, it may be said, to the osteo-arthritis and other forms of rheumatic gout in the remarkable maintenance of good general health during even many years of a painful and crippling inflammatory disease; and, further, there appears some relationship to cancer in the singular frequency with which cancer or sarcoma occurs in the healthy bones or other parts of those who have suffered for many previous years with osteitis deformans.

Thus, I imagine, by inherited dispositions, accumulating and combining or converging in definite proportions, this disease may be produced. I would try to imagine the genealogy of M. Charcot's disease, but that I have too little clinical knowledge of it. I can only suggest a combination of osteo-arthritis with syphilis chiefly localized in some spinal nerve centre; but I believe far better suggestions may be made by those who, suspecting a combination of diseases rather than many radiating from one source, will carefully study the essays of Professor Charcot and Dr. Buzzard's admirable clinical lectures on Diseases of the Nervous System. Besides, I may seem to have guessed already more than enough. Let me, therefore, say that even if my guesses are wrong, my error cannot weaken the probability of the belief that these and other rare diseases of like kind are instances of settled varieties of diseases, severally due to variations and convergence of morbid conditions in hereditary transmission. And if this be in any measure true, or even not more than a reasonable hypothesis, then it must be of great importance that we should know much more than we yet do of the variations which, in progress of time, diseases, or certain examples of them, may undergo; of their deviations in a gradually increasing number of instances from typical or standard forms; their acquirement in those instances of other comparatively fixed and long-abiding characters; of the occasional disappearance of old forms of disease, and the evolution of new ones. Such variations in diseases should be studied as Darwin studied the variations of species. Let me be clear in saying, as Darwin studied; for in the pursuit of new knowledge he may be a

model to all, as he has been to me so far as I could imitate him. He, as I know, would have studied these things, not by deduction, as from a law exactly formulated and from which he could trace the course of every change, but by a most careful collection of facts, facts to be seen in specimens and read in full records, and stored in museums, and by a study as complete for every case as if no law of evolution had ever been discovered.

Let me add that the study of these variations of diseases is not one of mere pathological curiosities. It may be of great practical utility; let me show how, if only that I may provoke some to pursue it vigorously to whom mere pathology is not attractive. We hear much, and often, of the uncertainty of medicines; of disappointments in the use of this or that supposed remedy; and substances which have long been in good repute for the treatment of this or that disease are spoken of with disrespect. It need not be questioned that in many cases the belief in the utility of a medicine has been maintained by completely erroneous observations. Such was the belief in the utility of infinitesimally small doses of anything ever yet swallowed. And other beliefs less evidently absurd may have been nearly as ill-founded. But there are many of which this is not to be said. It cannot be doubted that bromide of potassium is often very useful in epilepsy; yet sometimes, as we say, it fails; or that guaiacum is useful in some cases of chronic rheumatic arthritis, and is in others very disappointing; or that arsenic sometimes does and sometimes does not do good in cases of lymphadenoma. I suppose there is not a medicine in the pharmacopoeia which does not sometimes disappoint him who gives it hopefully; not one which is not, therefore, spoken of with contempt or blame, as if it were a responsible agent convicted of default. But here is an unfair imputation. It is not these medicines which are in fault but ourselves. That which some call the fallacy of therapeutics is generally the fallacy of diagnosis. To state the facts roughly, we suppose cases to be alike which are really different; and, very naturally, the medicine that does good in some of them is useless in others. For example, in the group of cases which I chiefly have in view, we do not always discern when a disease has varied so far from its usual type that it is no longer amenable to its usual remedies. A better diagnosis must precede a better therapeutics. We need not only the diagnosis between diseases essentially different, but that between the different and varying forms of each of those which we call by a generic name; and beyond this, we need a more exact power of what may be called analytic diagnosis; for there are few simple cases, and in those which are not simple we need to be able to discern all the components, and the proportions in which they are mingled or combined. Better treatment will follow better diagnosis, and better diagnosis will certainly follow a more exact pathology.

Let me illustrate this with an instance which is besides of some interest in the study of the variations of transmissible diseases and of the utility of museums. Questions are often asked as to changes which syphilis may, in course of time, have undergone; and, especially, whether internal organs were always, as they are now, liable to its attacks. It is hard to answer such questions on the evidence of any existing records; indeed, I might cite the whole history of syphilis as an instance of the insufficiency of records for the tracing of the natural history of diseases. But here is something suggesting what museums may do: a portion of muscle preserved by Hunter, and at least a century old, in which are morbid changes which may be safely referred to syphilitic gumma. Probably

similar evidence may be found in other museums; and there are other facts significant of the existence long ago of these internal syphilitic diseases, as well as of the improved treatment following better diagnosis. Fifty years ago, at the beginning of my professional studies, it was the custom, as it long had been, to give mercury not only in all recognized syphilitic cases and in most acute inflammations, but in a large number of cases of which one could scarcely say more than that they were all chronic and all obscure. Especially there were many such cases of what were considered chronic inflammation of the eyes, and of the brain and spinal marrow, the liver, and the testicle. To all of these cases it was customary to give mercury till, as one said, "the mouth was touched," and thus some were cured, and some uncured, and some harmed. The cures were enough to keep the mercury in such good repute that it was given more and more generally; and then the disappointments, as they were called, became too many, and the mercury was blamed, and was almost disused for chronic inflammations. But, meantime, a more exact pathology, a pathology more exact both in its morbid anatomy and in its clinical studies, was discovering the previously unsuspected syphilitic diseases of internal organs; and with this better pathology there came a better diagnosis, and with the better diagnosis a more judicious use of mercury, and good reason to believe that the chronic and obscure cases which mercury used to cure were those of syphilis overlooked. The case is an exemplary one of the relations between the true pathology and the right treatment of diseases, exemplary not only for encouragement, but for method of study; for the study was both clinical and anatomical, in the living and in the dead, with records and with specimens. Such must be our study of all the cases which I have chosen to speak of—the cases in which diseases deviate from their usual type, or combine in various proportions, after the manner of hybrids and mongrels or new chemical compounds. But there are some rules in study which are especially applicable to these cases.

1. We should very carefully study all cases which are not according to an admitted type. We should study all exceptions to rules; never thinking of them as unmeaning or accidental. Especially we should never use, in its popular, but wrong translation, the expression "exceptio probat regulam;" as if an exception to a rule could be evidence that the rule is right. If we use it, let this be in its real meaning; translating it, as surgeons should, that an exception probes a rule, tests it, searches it—as the Bible says we should "prove all things"—to its very boundary. In this true meaning the words may be an excellent motto for the study of all diseases that deviate from types.

2. We should look for indications of the existence in the same person of two or more morbid conditions or dispositions such as may be derived from both parents or from several ancestors. For, as in plants and animals there are hybrids and mongrels, or, as in chemistry, many compounds and mixtures, so are there in diseases. We see them in the multifarious varieties of what we have to call rheumatic gout; in gout crossed with scrofula, and syphilis crossed or mingled with scrofula or with gout. It is often not difficult to discern some of these combinations among our cases, and I know few things in practice more useful than to be able, even in some instances, to adjust our treatment to the proportion of each disease in the compound. But we may be sure that there is much more to be learned in this direction; and it is best to believe that we rarely have to do with a

simple and unmixed morbid constitution. There are few worse habits in practice than that of commonly saying of our case "It is all gout," and of another it is all scrofula, or all syphilis. We might as well say of any Englishman that he is all Norman, or all Anglo-Saxon, or all Celt. We may, indeed, sometimes see persons who appear to be as types of races unchanged in many centuries, but in practice we had better study every man as, for better for worse, a composite of many ancestors.

3. We should have for all these cases a much more complete and exact study of all the personal conditions of disease than is now usual. Of course this should include all that can be learned of each patient's family history; though there are few parts of medical inquiry more fallacious than this often is; and at the best it will need, besides, the exactest study of the patient's self. Perhaps the brilliant success which has been achieved by the recent studies of disease-producing organisms or other materials acting on us from without—a success not equalled in any other field of medical inquiry—has made some think too little of those changes within ourselves which occur in such ordinary conditions of life that they may be called spontaneous. Yet these are not less important in the production of diseases, and these must be studied; just as in agriculture soils must be studied as well as seeds. This is true even in respect of those diseases whose essential causes are most evidently external, even of those which are due to specific contagia; their germs or seeds, if I may so speak, will not germinate in an unfit soil. I suppose there is not a day in which most of us do not inhale or come in contact with the germs of some frequent or contagious disease; but they do not germinate in us any more than do the seeds of tropical flowers in our streets or in the fields to which the wind scatters them; we do not offer the fitting soil. And even among those in whom they do germinate, the product varies according to the soil. And the study of this soil, this living soil, is yet more necessary in respect of diseases which come, in part or wholly, by inheritance; for it is in each as personal and distinct as any other constituent of personal character, and the study of it must be intimately personal, with an exact analysis of every disposition to disease. The aim of pathologists in this direction should be for knowledge like that of the keen family practitioner, who, as he says, knows the constitution of every member of a family.

All this is equivalent to saying that these variations in diseases must be studied both in practice and in scientific pathology. It is hopeless that either a practitioner who thinks lightly of pathology, or a pathologist who thinks lightly of observant practice, should do more in the study of these questions than attain to that measure of partial truth which is often as deceptive as error. Each must be tested by the other. The living and the dead must be alike and equally studied; and the dead must be studied in exact observations, with accurate records, and especially with museums.

I need not dwell on the value of good records, good descriptions, and good photographs, or other representations of diseases; but they never have been and, probably never will be, enough. We need, with them, museums in which changes of structure may be preserved for repeated and revising study and comparison. For instance, in regard to the group of diseases of which I have been speaking, we ought to have in our museums specimens in which we might study all the gradations of change of structure from type to type, all the changes due to mingling of forms, all varieties of diseases, all hybrid forms. We need to be able to

study all these things, as the naturalist or the comparative anatomist needs his specimens; not only for teaching what is already known, but for continued re-examination and continued addition to his own knowledge.

And for complete study we must have large museums showing the coarse naked-eye characters of diseased structures. I am sure no one will think me likely to depreciate the microscope; it has added, and will continue to add, more than can be told to our knowledge; but it has not diminished the value of other evidence; and in pathological anatomy, as in all our sciences, there are many instances in which the naked eye sees facts with more meaning than the microscopic one can.

This is, especially, true in the case of morbid structures resulting from nearly allied diseases, and, therefore, especially true for those of which I wish to urge the study. In morbid structures as in species the nearer the alliance the less are the differences to be found in minute structures, and the more must we depend for distinctions on the study of visible shapes, and sizes, and constructions. I suppose that we could not with the microscope distinguish the human skeleton from that of the monkey; certainly we could not distinguish one skull from another in all these varieties of national form which are collected in our museum. And so it is in many instances of morbid bone formation. I doubt whether microscopic examination could detect characteristic differences in each of this group of specimens. With the naked eye it is sure that this is a syphilitic node on a tibia, and this a growth beneath a chronic ulcer over the shin, and this a pedicled exostosis, or ossified cartilaginous outgrowth from the shaft of a long bone, and this an instance of osteo-arthritis, and this a portion of the skeleton of an osteo-sarcoma or osteoid cancer.

Moreover, it is to be observed that in morbid structures, as in those that are natural, in the same proportion as the aggregated elements of embryonic structures acquire their complete and final form, so do the bodies composed of them acquire distinctive shapes and methods of construction plain to the unaided senses. The ova of many species may seem alike both in outer shape and in their component elemental structures. But in proportion as these structures are differentiated, and developed into their higher and abiding forms, as into nerve fibre, and muscular fibre, and the rest, so the larger characters of even the nearly allied species—the characters of shape, and size, and appropriate construction of the whole body, and of each part of it—become more and more different; and these constitute the real distinctive characters of each species.

And so it is in morbid products. The acquirement of distinctive shapes and methods of construction coincides with the development of elemental forms. For example, in these sarcomata are only the lowest elemental structures, round cells, spindle cells, and shapeless plasma; and the masses thus combined are shapeless, featureless, decisive by negation. But in these fatty and fibrous and cartilaginous and bony tumours, in which the elemental structures have advanced to higher forms, the masses which they severally compose are almost as characteristic and distinct in visible shape and construction as are the several normal organs of the body.

In every case, then, both the largest and the smallest characters should be studied. The naked eye can discern one set of facts, the aided eye another; both are essential to complete knowledge; no one should be content with either, for neither is alone sufficient. So we must have large specimens as well as small ones, and certainly large

ones for the study of the gradual variations of diseases as they deviate from typical forms, and become variously mingled.

And now, as I come near to my term of time, let me, as is customary in certain other places, conclude with an earnest appeal to your liberality. We want liberal contributions, not of money, but of specimens to our museum. We want specimens of many kinds; of course we want whatever is rare, but not these alone; we want some to complete our series of typical specimens; and, to keep to the chief subject of my lecture, we want the opportunity of choosing among many of what are called "bad specimens." We are all too ready to collect what are called good specimens as being well-marked instances of the standard characters of diseases, and to put aside as "bad" those which deviate from those characters, just as, clinically, we speak of good and bad cases of a disease. Of course, good specimens, typical specimens, must be at hand for the teaching of pupils who have to study illustrations of the accepted descriptions of diseases; but it is among bad specimens, even as it may be among exceptional cases, that those who are past pupilage, though they have not ceased to be students, may study the variations of disease. I ask the more boldly for contributions to the pathological collection because of its present satisfactory condition and the activity of work in it. You will soon see it in the repaired and renovated building. Looking at the number and value of the specimens and the wide range of pathology which they illustrate; looking at the interest of the history of our science which is told in many of them; at the memorials of Hunter and Matthew Baillie, of Astley Cooper, Liston, Howship, Lawrence, Hammick, Fergusson, Hilton and many more; looking forward to what the museum will tell of the researches and skill of those who are still with us, and among whose names I venture to feel sure, Mr. President, that none will take precedence of your own, while men study the specimens with which your skill and just audacity in operating have enriched the series of diseases of the ovaries and uterus: looking at all these things, and then at the perfect order and condition in which the specimens are preserved, I feel that the collection is one which all we members of the College may feel personal pride in calling our own, and should feel a personal duty to enrich. And its utility is being constantly more appreciated. I have been often made happy by the contrast which I have seen while working at the new edition of the catalogue. While I was writing the last edition, between thirty and forty years ago, scarcely a student ever entered the museum. Hour after hour I sat alone; I seemed to be working for no one but myself, or for nothing but the general propriety that a museum ought to have a catalogue, though no one might ever care to study with it. Now, and for some years past, a day rarely passes without many pupils and others being at work in every part of the museum.

All this is good; but much more is to be done. Our museum should be, even more than it is, the centre in which all pathologists may find help in searches after that which is not yet known; in such searches, for example, as may lead to a complete knowledge of the variations of diseases. For many years, even from the beginning, the anatomical and physiological departments of our museum have been not only a noble collection of specimens, but, through the renown and learning of its conservators, a great centre of teaching. Scientific men, especially comparative anatomists and anthropologists, have known that here, if anywhere, they could find whatever help a museum and a master in those sciences could give. A fort-

night ago the President of the Royal Society, presenting one of the royal medals to Prof. Flower, said: "Professor Flower has been for more than twenty years conservator of the museum of the Royal College of Surgeons; and it is very largely due to his incessant and well-directed labors that the museum at present contains the most complete, the best ordered, and the most accessible collection of materials for the study of vertebrate structures extant."

It is not for me to praise the pathological collection with similar words. But great as may have been its utility hitherto, we may be confident that it will henceforth be more useful than ever. In the vast increase of the biological sciences it became impossible that one man should be nearly complete in the knowledge of both natural and pathological anatomy. I say impossible. I believe there is not such a one living; if there could have been one it might have been Mr. Flower. Now, we may hope that labors as "incessant and well-directed" as his will be devoted especially to the pathological collection.

It is known to many of you that Sir Erasmus Wilson, in his usual liberality, gave the College £5,000, of which the interest should be spent in the promotion of pathology; and he agreed that this would best be done by helping to the appointment of a curator of the pathological department of the museum; and we have an admirable one. Mr. Eve is a worthy colleague and helper of Mr. Flower, excellent like him not only in knowledge, but in that which is even more rare, the love of museums, and of all that belongs to their maintenance and illustration, even to the making of catalogues. In all these good qualities he has distinguished himself at St. Bartholomew's. I believe that we may rely on him for making so good use of the museum, and of all that can be brought to it, that the College shall be the chief centre for the study of pathology, even to the furthest point at which it can be studied in specimens of diseased structure. I beg your help that he may be so; and if I shall have helped to-day to this good result, the first Bradshawe lecture in our College will have well fulfilled the purpose of its founder.

Original Papers.

ON TRANSFUSION.

By J. F. LE PAGE, L.R.C.P.E.

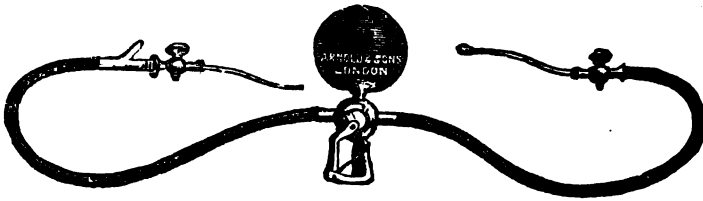

CONVINCED that in the conservative practice of the future transfusion will hold a place of no little importance, and will be more and more extensively resorted to, and seeing that the means at present at our disposal for the performance of the operation are not altogether satisfactory, I have devised an apparatus in which there is an endeavor to combine absolute safety with great facility in use.

Of the transfusers which have been at our service that of Dr. Aveling is, perhaps, all things considered, the most serviceable; but it has the disadvantage of requiring very complex manipulation. To put it concisely, each of them requires in its use for the surgeon to be aided by skilled assistance, whilst at the same time there is no safeguard against the injection of a minute quantity of air, however careful and adept the operator may be; an accident which, in all probability, would prove fatal to the patient.

The accompanying illustration shows how these disadvantages are overcome. One hand alone is needed to operate the transfuser, and the other

hand is at liberty to attend to the efferent tube; whilst the attention of the surgeon may be divided between the recipient and the donor of the blood. If any portion of air should at first remain adherent, and, of course, unseen, on the inner surfaces of the tubes, and, during the passage of the blood, be carried along with the stream, their course is with certainty arrested by the glass air receiver, into which they must rise. As to the *modus operandi*: The case contains the apparatus, knife, forceps, and a small bottle, which latter is intended to hold a compound powder composed, say, as follows: Carbonate of soda, ten grains; phosphate of soda, two grains; chloride of sodium, thirty grains. One-fourth of the powder should be dissolved in about two ounces and a half of water at a temperature of 100° F. A few drops of alcohol may be added, and the vessel containing the solution placed in another vessel partly filled with water at a temperature somewhat higher. Then, having attached the receiving and delivering tubes, the two extremities of the instrument must be placed in the inner vessel with the air chamber downwards. Now press the lever, press the elastic ball, release the lever, release the elastic ball, and, after repeating that process once or twice, turn both taps. It is now ready for use. Raise the patient's arm to the horizontal position, so as to

where a main artery has been divided. With its aid life may at least be prolonged, where the stomach and rectum refuse to retain nutriment in the exhaustion from marasmic disease. It may also be resorted to in the asphyxia of new-born infants, the injection being made through the umbilical vein, having previously allowed a little blood to escape from the umbilical artery. For this purpose a small quantity of blood taken from the placenta and defibrinated will answer very well. In chronic as well as in acute anæmia we may transfuse, for where the whole blood is altered by toxic or pathological causes it is manifestly advantageous to improve its quality by the admixture of healthy blood. It may also appear indicated after hæmorrhages from the stomach and intestines, hæmoptysis, and some surgical operations. I would go so far as to suggest, on physiological grounds, its occasional indication in hæmorrhagic fever. In the young who are robust, absorption and nutrition will soon replace the normal quantity of fluid, although for a time it will be inferior in quality to that which was lost, containing less than the due proportion of oxygen carriers, the red corpuscles. In those previously suffering from anæmia, and in the aged whose blood is very slowly reproduced, it appears to me that the operation may, with very great promise, be repeated

facilitate the transmission of the blood to the heart, and, having inserted both tubes, one into the supplying vein, and the other into the receiving vein—the right median basilic is, perhaps, the best—turn the taps, and, in the same order, press the lever, press the ball, release the lever, release the ball, and so on. Precisely one quarter of an ounce passes out each time. It is expedient, having commenced the transmission of blood, to complete the process without arrest, lest coagula should form. The apparatus is made by Messrs. Arnold & Sons, and their name is quite sufficient guarantee for excellence of workmanship. I must, however, say that my thanks are due to them for so faithfully, so well, and with such precision and care elaborating from my drawings an instrument of some elegance.

A word as to the cases in which transfusion is indicated. My special intention is that of supplying the obstetrician with a safe and facile means of transfusing blood after post-partum hæmorrhage, where the diastolic system is practically dead, and the heart is dynamically incapable of action in consequence of the absence of fluid to act upon. But transfusion is indicated in many other cases than that of uterine hæmorrhage leading to this condition. For instance, when, after excessive hæmorrhage, the vital fluid is not reproduced, and the nutritive process is so impaired that the persistent anæmia would be the forerunner of phthisis or other grave disease did we not supply red corpuscles to carry oxygen with which to re-establish those functions which are essential factors in the formation of hæmoglobin. And it is certainly indicated in some cases of hæmorrhage from the bursting of an aneurism, or

even more than once, at intervals of a few days. In cases of poisoning, when the nature of the poison is unknown, or when an antidote would not be effective, or in pyohæmia, might not occasionally a life be saved by alternate depletions and injections of pure blood? In epilepsy it has been used with marked success. And, as in puerperal eclampsia we may presume an excess of carbonic acid and a deficiency of oxygen, may we not here also find it of no little service? I should remark that Dr. Schäfer has most conclusively shown that the action on the blood-corpuscles of beef peptones, milk, and some other fluids, when used in lieu of blood, is most injurious.

It has been urged in disparagement of the operation that during transfusion very painful symptoms are experienced, followed, after its performance, by alarming prostration and hæmorrhagic fever. This we may admit to be, in some cases, substantially correct. But what is the cause of all this, but that the vital powers are so stimulated to reassert themselves that the heart and arteries, certainly with intermissions, are making very violent efforts to drive along the small quantity of blood which the system contains? The inference is clear that this most valuable operation has not been so frequently performed as it should have been, and that many invaluable lives have been lost which might have been saved by the immediate restoration of the failing powers of the heart and nervous system which it most strikingly effects.

THE PATHOLOGY OF THE BLOOD IN INFLAMMATION.

By JAMES T. R. DAVISON, M.D. Edin.,

Senior House-Surgeon, Royal Southern Hospital, Liverpool;
Late Resident Physician, Royal Infirmary, Edinburgh.

THE results obtained from the examination of some hundreds of specimens of pathological blood justify me in enunciating, as a pathological law, that "during the active period of inflammation the leucocytes of the blood are increased in numbers." The behavior of the leucocytes under the inflammatory influence constitutes a most important help towards finding out the existence of inflammatory lesions. I need only mention those cases of obscure internal abscesses and the first stages of pneumonia as examples of conditions where occasionally it is next to impossible to recognize them with certainty, and where the examination of the blood may lead us a good way on towards arriving at a certain diagnosis. This alteration of the blood is, for practical purposes, more important than the "hæmatoblastic crisis" described by M. Hayem, for while the latter comes into play at or about the time of the crisis of acute disorders, the former exhibits itself from the very first, even within a few hours from the commencement of the inflammatory process. Thus while the "hæmatoblastic crisis" may for prognostic purposes be interesting, as indicating a favorable course of the disease, it possesses no diagnostic value; but the increase of leucocytes, by indicating the existence of an inflammatory process, and that from the very first, has a great diagnostic value, while it also is an element in prognosis, for the subsidence of the inflammation will be followed by a decrease of leucocytes.

It is well known that the leucocytes are found in greater numbers in the blood during the digestive process. How is this brought about? There is no necessity to assume that this increase is due to a more active formation of leucocytes in the spleen and other blood-forming organs. Recent pathology would favor the view that the increase of leucocytes in the blood is brought about reflexly by increased contraction of the splenic muscle and probably also of the lymphatic muscles, the point of origin of the reflex action being the gastro-intestinal canal. It has long been known that the spleen was capable of muscular contraction, and it has been left to Dr. Roy recently to discover that this contraction is rhythmical in time, and the directions through which nerve force influences this contraction. Dr. Roy believes that the spleen contains a nervous mechanism which regulates its contraction, but he has shown that this contraction is also affected by nerve influence from without—for example, stimulation of the peripheral end of a cut vagus causes contraction of the organ.¹ It is therefore probable that the contraction of the gastric muscle during digestion stimulates the pneumogastric; that a nerve force is then carried to the medulla oblongata (Dr. Roy showed that stimulation of the vaso-motor centre in the medulla brought about contraction of the spleen), and thence is reflected through the vagi and splanchnics to the spleen, giving rise to increased contraction of its muscle, and thus to a discharge of leucocytes into the circulation. These leucocytes having performed their function, whatever that may be, probably return into the spleen and lymphatic glands, as they are no longer found in excess in the blood after the digestive process is ended.

Once admitting that the spleen can be made to discharge its leucocytes into the blood by a reflex

action originating in the gastro-intestinal canal, and knowing the intricate and complicated connections which exist in the sympathetic system, it will not be difficult to understand that the spleen can likewise be made to contract reflexly by a force originating in the arterioles and capillaries of any part of the body. In the inflammatory area a force—whether it be chemical, resulting from altered nutrition of the tissue cells, or nervous, reflected from a distant part—paralyzes the vaso-motor nerves of the arterioles. Either this same force, or one originating in the walls of the arterioles—the result of distension caused by increase of blood-pressure in the inflammatory area—is carried to the medulla, and thence reflected to the spleen, and thus the spleen is advised that migration of leucocytes is taking place, and a call is made upon it to supply the demand made upon the blood. In inflammation there is therefore a loss of leucocytes from the blood, and an effort of nature to replace them, but, as in the case of hyperpyrexia, nature overdoes what is required of it; so here the supply from the spleen and lymphatic glands is greater than the demand, and therefore it is that during the active period of inflammation we find the leucocytes in the blood in such increased numbers.

The simplest form of inflammation that can be selected for examination of the changes in the blood is an abscess, for here there can be no suspicion of other influences being at work other than the inflammatory. If the abscess be acute and large the leucocytes are found in great abundance in the blood; but if the abscess be chronic, although it may be large in size, the leucocytes are not increased to such an extent. In the one case there is an active migration of leucocytes from the capillaries, and a consequent active demand upon the spleen and lymphatic glands; in the other case the migration is passive and small in quantity, and therefore the blood-forming organs are not called upon to supply a large amount of leucocytes. Small abscesses may also give rise to an abundant increase of leucocytes, and at other times to a slight increase only. Probably this difference depends upon the amount of tension and inflammatory fever present. In a case of abscess of the finger which had lasted for nine days, a small quantity of pus being present, but where the patient had passed sleepless nights, I found more leucocytes in the blood than in another case where a chronic abscess containing several ounces of pus had lasted for some months. After abscesses are opened the leucocytes in the blood begin to disappear, but sometimes the defervescence of these cells is interrupted by a secondary increase. When an abscess is opened tension is relieved, and the inflammatory process subdued, and the defervescence which then takes place is in accordance with the principle stated above, the demand for leucocytes being no longer present. The occasional secondary increase of these cells can easily be accounted for by an exacerbation of the inflammatory action. Next in importance to abscesses are scalds and burns, for in these we have an acute inflammation with visible effusion, which develops itself in a very short time, and thus we have an opportunity of examining the blood almost at the commencement of the inflammation. The leucocytes are always increased, and this increase I have noticed as early as two and a half hours from the application of the irritant, clearly proving that the blood-forming organs have acted reflexly and emptied themselves of part of their contents, for in such a short time as two and a half hours the spleen and lymphatics could not have formed all the extra leucocytes found in the blood. In cases of severe scalds and burns the excess of leucocytes

¹ Journal of Physiology, vol. iii., No. 3.

may last for a long time, as a pus-secreting surface is left, and hence the migration of leucocytes continues. The same conditions exist in old discharging extensive surfaces, and the same excess of leucocytes is found in the blood. Again, the same principle is manifested in inflammation of serous membranes. In pleurisy the leucocytes may be present in very large numbers, diminishing with the lowering of the temperature. In pleurisy, as in other inflammations, a return of the temperature to normal is not immediately followed by a sudden and rapid decrease of the leucocytes. It is easier for the white corpuscles to enter the circulation than to leave it. Doubtless the lowering of the blood-pressure which takes place at the crisis of an acute inflammation favors the return of the leucocytes from the blood, for the consequent retardation of the peripheral circulation is the nearest physiological approach to pathological stasis, and thus the leucocytes are placed under the best possible circumstances to attach themselves to the capillary walls, and eventually to regain the lymphatic system. Still this cannot take place in a short time, and it is, therefore, that the inflammatory crisis is not immediately followed by a sudden and rapid decrease of the leucocytes. In peritonitis and acute bursitis I found the white corpuscles in excess. In a case of double effusion into the knee-joints four days old, with a temperature of 100.4°, I did not find an increase of the white corpuscles, and here I may state that my examinations hitherto have been made without the aid of the hæmacytometer, so that what I have observed was what was obvious to any eye educated to estimate the normal amount of leucocytes by glancing over different parts of the field, and thus when the increase of leucocytes was very slight, it would have been unappreciable to the eye; and in this way I must account for the apparent absence of the excess of leucocytes in this case, bearing in mind at the same time that a small migration of leucocytes, apart from tension and inflammatory fever, will call for a small supply from the blood-forming organs, and as the effusion subsided in this case, the amount of white cells it contained must have been small. Somewhat similar to this case are those of chronic synovitis of the knee and hip, and of chronic swelling of rheumatic joints. In all these instances the serous membrane is inflamed, but the inflammation is passive, the migration of leucocytes small, and hence in the blood we find the white corpuscles either normal in quantity or only very slightly increased. In acute rheumatism the white cells are always increased; sometimes the increase is very slight, and sometimes very abundant, and it appears that the greater the number of joints swollen, provided the swelling is accompanied by pain, the greater is the increase of leucocytes—that is, the increase of the cells keeps pace with the extent of the inflammatory serous surface. Once more, in inflammation of the mucous membrane the same principle is manifested. In acute bronchitis the excess of leucocytes subsides with lowering of the temperature and decrease of expectoration (if purulent); but if the temperature comes down and the expectoration remains of the same quantity the excess of leucocytes is not affected. It appears, too, that the leucocytes increase more when the expectoration is green than when it is of other kinds. The same increase is found in inflammation of other mucous membranes—in diarrhoea, dysentery, acute laryngitis, and cystitis. The results obtained from the examination of the blood of phthisical patients have been very interesting. The leucocytes are sometimes very abundant. I found that whenever high temperature, green expectoration, and auscultatory accompaniments were present together, the

increase of leucocytes was well marked. On the other hand, if there were no accompaniments on auscultation and the expectoration was not green, even if the temperature was a little above normal and profuse night sweats were present, the increase of leucocytes was very slight. This clearly proves that the increase of these cells in phthisis is not the result of the cachexia, but is determined by an inflammatory action, or by the activity of pus-secreting surfaces of cavities, this latter action being practically inflammatory as regards the migration of leucocytes. In pneumonia the excess of leucocytes is generally very marked, and is thus of great diagnostic value. Lastly, in acute inflammation of other organs the same excess is noticed—for example, in tonsillitis, orchitis, eczema—and even in the inflammation excited at the seat of fractures of long bones.

The morphological origin of fibrin formation has been established by Dr. Norris. Of this he has afforded both positive and negative evidence; for he has photographed the invisible corpuscles in the act of becoming fibrin,¹ and he has also found that a pure filtrate of blood, containing no morphological elements, does not undergo coagulation.² According to Dr. Norris, the cells which become fibrin are the primary lymph cells, the invisible corpuscles (nuclei of the former), and the faintly visible undeveloped red corpuscles (a further development of the second.) Partial confirmation of this origin of fibrin formation is adduced by Bizzozero, who ascribes the formation of fibrin to his blood-plates (primary lymph-corpuscle of Norris), and by M. Hayem, who ascribes the same formation to his so-called hæmatoblasts. But both these observers look upon their respective elements rather as determining centres of fibrin formation. That fibrin is present in the inflammatory exudation has been shown by Dr. Burdon-Sanderson, who states that in inflammation of the mesentery the fibrin can be seen on the surface of the membrane.³ It being established, then, that fibrin is present in inflammatory exudation, and that fibrin is a rearrangement of cells and nuclei of the blood, it follows that in inflammation these fibrin-forming cells and nuclei migrate from the capillaries as well as the leucocytes, and this migration of fibrin-forming elements must be accompanied by an increase of their number in the blood on the same principle that a migration of leucocytes determines an increase of leucocytes in the blood. The question arises, How are we to know that the fibrin-forming elements are in excess in the blood? Now, there can be little doubt that the hæmatoblasts described by M. Hayem are the granules caused by the disintegration of the undeveloped red corpuscles.⁴ No one has seen these granules in the circulating blood, but they have always been observed in shed blood. Dr. Norris has shown that human blood examined on the cold stage of the microscope is free from these granules, while it contains them when examined under the ordinary temperature. This is pretty clear evidence that the granules can be formed after the blood is shed. But Dr. Norris has given positive evidence of their formation, for he has photographed the undeveloped red cells in the act of becoming disintegrated. The evidence afforded by micro-photography cannot be gainsaid. What cannot be discerned by the unaided microscope can be brought out by photography; there-

⁴ The Physiology and Pathology of the Blood (Norris), section iv.

fore this kind of evidence is superior not only in that it reveals objects just as they really exist, but in that it discloses more of them. The fact that these granules are formed after the blood has been shed does not exclude the possibility that they may also be formed in the circulation under pathological conditions; indeed it seems very probable that this does actually take place sometimes, as evidenced by the enormous quantities of granules present in certain states. Whether, however, these granules be found in or out of the circulation, or, as is more probable, under both conditions, it is evident that they are formed from the undeveloped red corpuscles; hence we may fairly take the number of granules as an index of the number of undeveloped red cells, and, as these latter cells constitute one of the fibrin-forming group of cells, we may roughly estimate the number of fibrin-forming elements in the blood by the number of granules present on the microscopical slide.

In acute large abscesses I have sometimes found the granules present in great abundance; at other times, though in excess of the normal, this excess has not been marked. I found in some cases, of acute abscesses, where the excess of granules was marked, that after the abscess was opened the granules diminished in quantity, and after a time again increased. This fact is very interesting, as showing that the increase of the granules in inflammation is determined by two principles. In the first instance the determining cause is the same as that which obtained in the case of leucocytes—namely, a migration of fibrin-forming elements from the capillaries, and a consequent demand by the blood for more of these elements. It may be objected that as no fibrin is seen in pus, therefore there can be no migration of the above elements. Certainly if we examine pus from an abscess we do not find any fibrin in it, but then what about the pyogenic membrane? What is the pyogenic membrane? In the first place it may be remembered that Dr. Burdon-Sanderson has shown that inflammation is not "altered nutrition," as was once supposed, but that it is an "arrest of nutrition;" that it is not a constructive, but a destructive process.⁴ This fact would seem to disprove the idea that the pyogenic membrane is a connective tissue formed during, and as a result of, the inflammatory action; and even supposing that it were a connective tissue, its expansion as the abscess increased in size could not be accounted for, as ordinary connective tissue is incapable of the expansion that would take place in a large increasing abscess. Moreover, if the pyogenic membrane were connective tissue, an abscess could not enlarge, for this tissue would prove an effectual barrier to the migration of leucocytes. The explanation must therefore be that the pyogenic membrane is formed by the fibrin-forming elements which have migrated from the blood-vessels, and become conglomerated together on the surface of the abscess; that it is, in fact, the analogue of the layer of fibrin seen on the inflamed mesenteric surface. In the same manner must be explained the formation of membrane on the inflamed pleura and pericardium. The fact that these membranes often become organized does not destroy the assumption that they are formed from altered elements which have migrated from the blood, for the organization may be effected in the same way as Professor Hamilton describes the organization of a sponge inserted in a wound—viz., by the bloodvessels of the serous membrane being pushed into the substance of the fibrin. Thus we can account for the increase of granules seen

in the blood during the active period of abscess formation. When the abscess is opened tension is relieved, and migration is at least partially arrested, hence the decrease of granules in the blood at this stage. But the granules increase again, and this second increase I believe accords with the hæmatoblastic crisis of M. Hayem. M. Hayem has found (and his observations have been confirmed by M. Reyne) that about the time of the crisis of acute diseases these granules are increased in the blood, and their excess is ascribed to an effort of nature to repair the blood after the decrease is over.⁵ The state of the system after the healing of an acute abscess is somewhat similar to its condition at the crisis of an acute disease. In either case there has been tissue destruction owing to the high temperature, and therefore in either case a reparation of the blood would be profitable. The reparation of the blood would naturally be effected by an increased discharge of blood elements into the circulation, and as these blood elements would consist of undeveloped red cells, and as moreover one of the stages of the undeveloped red cell disintegrates into granules after the blood is shed, therefore we can easily account for the increase of granules seen in the blood at this period. But the first increase of granules I hold to be determined by a different cause altogether—viz., by the migration of fibrin-forming elements, for this increase takes place during the active period of the inflammatory process, and therefore before the repairing influence comes into force. At the beginning of pneumonia, pleurisy, peritonitis, cystitis, laryngitis, and bronchitis I have found an increase of the granule, generally a slight one, and a larger increase I have noticed about the time of the subsidence of the disease. These two increases, running into one another and apparently one, I believe to be as distinct from each other as they are in the cases of acute large abscesses. The reason why the two increases appear to be only one is that the first is generally slight, and a decrease of it would not be easily noticed, and this holds good also for some cases of acute large abscess. But in those cases of acute large abscesses where the first increase is very marked after the knife has been inserted and tension relieved, the decrease of the granules becomes obvious, as does also the secondary increase which takes place later on. There appears to be thus two waves of increase of granules in the blood in acute inflammation—the first being the manifestation of the supply of fibrin-forming elements of the spleen and probably lymphatic glands consequent upon the demand made by the migration of these elements; the second a manifestation of the supply of blood-cells by the same organs consequent upon the demand made by the system to repair the blood after the disease is over.

In conclusion, I do not mean to infer that the leucocytes of the blood are only increased during the active period of inflammation. It is well known that they are increased in leucocythæmia and after severe hæmorrhage, and I have found them increased in yet other conditions. What these other conditions are have yet to be ascertained. I have not a sufficient number of cases to justify me in making any generalization with regard to them, but I claim for the principle enunciated above an important place as an element in the diagnosis of inflammatory lesions, nor do I wish to state that the granules are only increased during the inflammatory process and at the crisis of acute diseases. I have elsewhere endeavored to show that causes which interfere with the development of the red

⁴ Laminar Lectures, 1882. Lecture I.

⁵ Archives Générales, de Médecine, Janvier, 1880, p. 123, Janvier, 1882, p. 104.

cells give rise to an increase of the granules in the blood, the increase in these instances being due, not to an extra supply of cells by the blood-forming organs, but to an arrest of development, whereby a good many cells do not become fully hæmoglobinized red cells, and as a good many of these disintegrate into granules, therefore under these conditions we find the granules in the blood increased in quantity.

LARGE ASYLUMS FOR THE INSANE.

By H. RAYNER, M.D.,

Superintendent of the Male Department of the Hanwell County Asylum.

It appears to be desirable to draw attention to a danger which threatens the welfare of the insane poor of England and Wales. This danger arises from the conversion of asylums of a size that is efficient and economic, into larger asylums that are less economic, and I fear less efficient. Moreover, valuable opportunities are being lost by the building of large, cheap asylums for the detention of lunatics, in place of efficient hospitals for their treatment and cure. These errors are being committed from the prevalent belief that large asylums are the cheapest.

The subjoined figures abstracted from reports prepared for other objects will, I hope, tend to correct this mistake, and prevent further mischievous consequences. The thirty-sixth Report of the

ment; and the two other divisions being made only to show the increase of cost with the increase of size.

The first table shows, as might be expected, that those asylums are dearest which are not sufficiently large to justify the necessarily complex and expensive staff of such institutions; and it also shows that beyond this is a class much more economic, and, if judged by the proportion of medical attendance supplied, much more efficient than the larger asylums.

A Parliamentary return for the year 1877 yields the statistics found in the second table.

This report includes all the county asylums of which the returns were available, and shows that the asylums of from 450 to 600 beds are the most economic in construction, larger asylums being dearer in proportion to their size; even Banstead, constructed in the simplest manner, with a special view to cheapness, being more costly.

A second Parliamentary return for the year 1877 shows that in—

Asylums of	The average cost of repairs of building per bed per annum.
Not more than 450 beds.....	£1.74
450 to 600.....	1.85
600 to 800.....	2.48
Upwards of 800.....	2.91

In this respect the cost would seem to bear a direct relation to the increase of size.

Statistics are proverbially unreliable, and I have

Commissioners in Lunacy for the year 1881 yields the following statistics in regard to the English county asylums. (The borough asylums are excluded as being under different conditions.) The asylums I have divided according to their number of inmates into four groups: the first, in which there are less than 450, being considered too small; the second, above 450 and under 600, being taken as the most favorable size for economy and treat-

considered these carefully, from other points than the one given here, with the result that, making all due allowances, I consider the above figures to approximate closely to the truth. Assuming that they do so, we may make the following summary of results, in comparing the moderate-sized asylums (450 to 600 beds) with the large asylums (of 800 beds and upwards). In the large asylums a patient costs 6½d. more per week, and each bed

costs £44.7 more in construction and £1.06 annually in repairs. This is equivalent to saying that if 40,000 patients (and the number for England is close upon this) were lodged in large asylums, they would cost £1,760,000 in construction of buildings, £40,000 annually in repairs, and nearly £60,000 annually in maintenance, more than the same number in asylums of the size I advocate.

The current economy is of small importance compared with the question of efficiency, and this depends to a very great extent on the personal influence of the medical superintendent, an influence which I believe cannot be delegated to a junior officer, however efficient and zealous.

The primary importance of the personal influence of the physician was emphatically expressed by W. Tuke in 1792, and was fully recognized by the Commissioners in Lunacy in their report for 1857, in which they point out "the evils of very large buildings on account of the loss of individual and responsible supervision, the loss of the patient's individuality and the tendency of the rate of maintenance to run higher." I could quote many other authorities in support of this opinion, but that I might appear to be proving a truism.

Then arises the question, Over what number of patients can an average superintendent exercise the maximum of personal influence, and at the same time exert such a general control over the asylum that every detail of management may be used to the greatest advantage for treatment and economy? I answer that the number should be not more than 600, and that the balance of advantage lies in a somewhat smaller number than this.

I do not doubt that efficiency may be and is obtained in the larger asylums, but, as the preceding figures show, at a much greater cost, which must be still further increased if the number of medical supervisors in them is to be made proportionate to that in the medium-sized asylums.

Believing as I do that the curability of insanity is in an almost direct ratio to the care bestowed on it, I cannot help expressing an emphatic protest against the enlargement of asylums of useful size, or the building of large dementia repositories in place of lunatic hospitals.

Haawell.

CASE OF FEIGNED SKIN DISEASE.

By T. COLCOTT FOX, M.B. Lond.

A. S—, aged nearly sixteen years, a furtive-looking general servant in London, presented herself at the Skin Department of the North-West London Hospital on the 28th of November, 1882. The catamenia commenced at the age of thirteen, but had since been irregular, and for the past year absent. She was fairly well nourished, but pasty-looking, and her finger-nails were markedly grooved. She applied on account of three excoriated patches which appeared on Nov. 21st, close together on the front of her left leg, and had, she stated, given her great pain, and caused her to lie awake sobbing at night, so that her mistress had no longer the heart to keep her at work. The suggestion had been made that the sores were caused by the dye from her black stockings, and the girl said that she had dressed the places with "Moore's ointment." One sore was perfectly oval, another nearly heart-shaped, and the third triangular, with a horn at each angle at the base. The patches measured about $1\frac{1}{2}$ in. by $1\frac{1}{2}$ in. to 2 in., and the long axis was in the direction of the limb; they were simple uniform weeping excoriations, with hardly any attendant inflammation. Sus-

pecting the nature of the lesion, I ordered a simple dressing and a saline aperient, and talked of admitting the girl into the hospital if more sores appeared. On Dec. 5th she returned with a transversely oval sore just above each mamma, a very characteristic site in feigned cases, but not quite symmetrically situated. There were two others above the left ankle-joint, and one on the outside of the right calf, all longitudinally oval simple excoriations, with a well-defined border, except on one sore, where the abrasion was not complete at one end, and only papulation existed, suggesting a cantharides application. There was a dark-brown blood scab on some. She was admitted to the wards. On Dec. 6th a transversely oval patch appeared just below the left mamma; and another, longitudinally oval, covered with a slight scab, on the right hip. The girl from time to time, for twenty-four hours after admission, had prolonged fits of hysterical sobbing. On the 12th a sore appeared on the right shin near the ankle, and another on the right mamma, between the site of a former excoriation and the areola. There was a remarkable uniformity in the size of the patches throughout. As to the agency at work, I never could detect any evidence of the formation of a bulla, and the patches were too superficial for causation by an acid; moreover, repeated examination of the clothes, bedding, etc., at convenient times and unbeknown to the patient, failed to furnish any clue. On the 16th, no more excoriations having appeared, I taxed the girl with producing the eruption artificially, and, after prolonged denials, she confessed that she had done so, partly by her nails, but mostly by continued rubbing with the tops of her fingers. Probably the malingering was not altogether motiveless, and she desired a rest from her household labors. She proved to be very troublesome and disobedient in the ward, and I learnt from her father that she was an incorrigibly bad girl and a constant source of worry. The case is of interest as establishing an agency which has hitherto only been suspected as possible. Whether the skin in these cases is peculiarly sensitive to injury is a point for further investigation.

Harley-street.

TWO CASES OF INTRA-VENOUS INJECTION OF FLUIDS FOR SEVERE HÆMORRHAGE.

By WM. COATES, M.R.C.S.,

Resident Accoucheur, Late House-Physician, London Hospital.

PROMINENCE having lately been given in THE LANCET to the subject of intra-venous injections for the purpose of combating the effects of severe hæmorrhage, in connection with which Mr. Jennings has contrived a new instrument, I wish to supplement what has already been written by the history of two cases in which I have performed this operation, both of them cases also interesting in these particulars, that the hæmorrhage necessitating the operation occurred a long time after delivery without any definite cause, and that they were the first occasions on which Mr. Jennings' syphon has been employed.

The first case is that of Emily C—, aged twenty-six, a patient of the London Hospital Maternity Charity. She is a married woman, has had five children, but has always been delicate. Has had heart disease for some years, having had rheumatic fever when young. On October 16th she was taken in labour early in the morning, and at 1 p.m. I was summoned to the case. The patient was feeble, pulse rapid and intermittent, and she had stenosis and incompetence of the mitral valve.

The head was low in the pelvis, in the second position, but as the pains were few and there had been no further descent during the last three hours, delivery was effected with Barnes' long forceps, and the placenta easily expressed. About twenty minutes after delivery violent hæmorrhage occurred. Manipulation, hypodermic injection of sclerotic acid, cold affusions, ice internally and externally, the intra-uterine injection of hot water, were all resorted to; but these measures failing to produce more than temporary uterine contraction, ten ounces of a solution of perchloride of iron (one in five) were injected into the uterus. The hæmorrhage ceased, and after the lapse of a little time the uterus contracted moderately. The patient progressed favorably, and seemed in a fair way towards recovery, when, contrary to instructions, she sat up for an hour on November 1st, and again began to flood. She was found in an anæmic weak state, but the hæmorrhage was easily arrested. Two days afterwards the bleeding returned, and the friends did not summon assistance until she had been "losing" for eight hours. When seen the bed was saturated with blood, and the patient appeared almost moribund. Pulse was only just perceptible at the wrist, and very frequent; skin and mucous membranes were almost bloodless, extremities and nose were icy cold, vision was dim, she did not recognize any one about her, and was seemingly unconscious. Although now quite still, her friends stated that she had been tossing violently. My colleague, Dr. Basil Walker, agreeing with me as to the necessity for immediate action, and the husband being unwilling to supply blood, Jennings' syphon was procured, and the saline alcoholic solution recommended by him in *THE LANCET*, and which is almost identical with that suggested by Mr. Little in the *London Hospital Reports* (1866), was allowed to flow into the radial vein, this being the only visible one and of fair size. The result was marvellous. Sight and consciousness returned, the pulse gradually but steadily improved, the patient expressed herself as feeling "beautiful," and soon was able to retain stimulants, which were freely administered. She had a good night, seemed better in the morning though extremely anæmic and weak, and the possibility of another outburst of hæmorrhage being entertained, she was brought into the hospital. With the exception that symptoms of acute mania appeared on November 17th her progress has been most favorable, and recovery is probably not very remote. To give some idea of the intensity of the anæmia it may be stated that retinal hæmorrhages have been observed in both fundi.

The next case is that of Mary C., aged twenty-seven, a patient of the same Charity. On November 10th she was confined of a healthy child after an easy labour. Her convalescence apparently proceeded rapidly. She sat up on the fifth day and performed household duties in a week. On the 19th, soon after straining at stool, she became faint, and then flooded alarmingly. At 1 p.m., half an hour after the onset of the hæmorrhage, the appearance of the patient betokened severe loss of blood, which was found in large quantity upon the floor and bed. The uterus was relaxed, and blood was flowing in gushes from the vagina. The os just admitted a finger, and the uterus was full of clots. Sclerotic acid, ice, kneading, etc., failing to arrest the hæmorrhage, the vagina was plugged, and patient brought to the hospital. When seen soon after arrival—2.30 p.m.—she appeared much worse, was vomiting, and complaining of abdominal pain. A large tumour was felt, reaching almost to the ensiform cartilage, which proved to be the uterus distended with blood, the constricted os evidently preventing its free exit. A digital ex-

ploration of the uterine cavity was now made—the large uterus and small os rendering this incomplete; but nothing abnormal, except a little roughening of the anterior wall, could be detected. Failing to check the bleeding, and wishing to ascertain its origin, the os was somewhat rapidly dilated with Barnes' hydrostatic bags. By this time, however, the state of the patient had become most critical. She said her sight was dim, and that she must die. The pulse was almost imperceptible; respiration was irregular; extremities cold; and there was jactitation. Mr. Unsworth, house-surgeon, concurring with me that there was no time to be lost, and no vein being visible, an incision was made over the situation of the median cephalic, and that vein exposed, into which about twenty-two ounces of simply warm water, at a temperature of about 100° F., were injected with the aid of Jennings' syphon. The result was no less striking than in the preceding case. The pulse became regular, ceased to intermit, and its volume increased; respiration improved; sight returned; and the uterus slowly but distinctly contracted; she at the same time expressing herself as feeling better. At about 4.30 p.m. Dr. Herman saw the patient, and, the os being now fairly dilated, the interior of the uterus was examined, but nothing further was discovered to explain the flooding. As there was still considerable bleeding, the uterus was swabbed out with a saturated solution of perchloride of iron, diluted with about equal bulk of water, and the patient was removed to bed. An enema of beef-tea and three ounces of brandy was administered; but in a short time she could swallow, and stimulants were freely exhibited. The patient is now progressing uninterruptedly towards convalescence, not having had a bad symptom, except a slight elevation of temperature (102° F.) the first few days.

I have pleasure in bearing testimony to the general efficiency of Mr. Jennings' instrument, and although on these occasions I was materially assisted by my colleagues mentioned and Mr. C. J. Dabbs, I believe the operation could have been accomplished single handed. One merit of the instrument seems to me to be that although the tube is very long, the fear of introducing air is reduced to a minimum by the situation of the hole in the cannula and by the arrangement of the stopcock and glass-interrupter. The fault that was noticed in it on these occasions—but this is one that can easily be remedied—was the sharp point of the cannula. As at present constructed, unless the greatest care were observed, not only would the point injure the wall of the vein, but it would penetrate through the whole thickness of the skin. It is needless to say that Jennings' syphon is altogether unsuitable for the injection of blood, and I believe it is not intended for that purpose, for although the blood be most carefully whipped, its passage through so long a tube would be almost certain to ensure the formation of coagula. As Mr. Jennings' elaborate instrument is not in the hands of every practitioner, it may be as well to point out that the same result might be attained by the use of an ordinary irrigating can, or even a piece of drainage-tube might be utilized to serve the same purpose—i.e., if a suitable cannula were first obtained to introduce into the vein, and this could be prepared out of a piece of narrow glass tubing.

It may appear strange that in the second case simply warm water was injected with a view of reviving the patient, but thinking that the great factor in bringing about reaction in these cases of collapse was by the introduction of some fluid into the circulatory system upon which the heart could contract, I determined to give water a trial. The

result speaks for itself. The resuscitation was no less marked in this case than in the one where alcohol and saline salts were employed in addition to the water. The omission of the saline salts in no way interfered with the success, and so a fluid of a different specific gravity, and one which is supposed physiologically to swell up the red globules and cause them to yield their pigment, was injected into the blood, and with a beneficial result. It may incidentally be mentioned that when microscopically examined, twenty-four hours afterwards, there was no obvious alteration in the appearance of the corpuscles. I am prepared to admit that if the fluid injected, in addition to increasing "the dynamic force of the circulation," combined with this the property of cardiac stimulation, it must be superior, but I am inclined to attribute the good effects of the injection far more to the former than to the latter cause; and with the return of consciousness and the renewal of the circulation, stimulants may be freely exhibited which previously are either unable to be retained or else, on account of the feeble circulation, cannot be assimilated.

The outburst of secondary hæmorrhage so long after delivery adds to these cases an especial interest, which is enhanced by the obscurity of its origin. If, as I am under the impression, having seen certain suspicious looking sloughs about the os whilst plugging the vagina, the hæmorrhage in the first case was the consequence of the separation of a slough formed after the use of the iron injection, in addition to the dangers which are attributed to the intratracheal injection of perchloride of iron, we are confronted by one which I fail to find alluded to in the ordinary text-books, and one which, though more ulterior in its appearance, is certainly not less fatal in its consequences. And naturally the question arises, Would the intra-venous injection have made the uterus contract as effectually as the perchloride of iron if it had been employed in the first instance? If it could be proved that such a performance would sufficiently reanimate the patient to bring about uterine contraction, then that course ought to be adopted; because, now that intra-venous injection has been reduced to a practical operation, the dangers of the latter appear diminished when compared with the former. But the issue of the second case shows that although the uterus does contract after intra-venous injection, it does not always do so sufficiently to arrest all hæmorrhage, as the perchloride had subsequently to be applied to completely arrest the flow. It may be thought that the hæmorrhage was the result of polypus, retained placenta, or other cause; but, although carefully sought for, no evidence of such was found. Getting up too soon was the probable cause of the hæmorrhage in the other case.

I am aware that final conclusions cannot be drawn from what may be called two isolated cases; but one thing, at least, appears to have been established—viz., that the operation of intra-venous injection is a practicable one.

In conclusion, I would thank Dr. Herman for his courtesy in allowing me to publish these cases: London Hospital.

ON SPINA BIFIDA.

By G. B. BARRON, M.D., M.R.C.S.

THE subject of spina bifida has been discussed of late in the columns of *THE LANCET*, and an unusual amount of interest has been evinced in its radical cure by the recognized methods of treatment. How far all cases may be found to be amen-

able to any treatment, or how far it is always justifiable to attempt so dangerous an experiment as that of injecting a cyst of this character, is yet beyond the domains of our knowledge. The cases of successful procedure are too limited to warrant any inconsiderate rashness in such a bold and heroic step as rushing in with some badly defined hope of success to stop the gap Nature in her fickle freak has omitted to close. The following case is a fitting one to record as illustrating how tolerant the nerve centres may be of unnatural processes, and how nerve functions may remain unaffected, contrary to our preconceived ideas of their integrity. The literature of hydrorachis is unsatisfactory, as authors, in treating of the subject, pass it over in a brief and rather off-hand manner. The best article on the disease is to be found in Cooper's *Surgical Dictionary*. Cooper relates some interesting cases, but anything like scientific lines of treatment whereon to act with confidence are even here wanting. I apprehend our best surgeons are divided in their opinions as to the most reliable method of dealing with it, and none yet dare issue a dictum of probable successful operation. Cooper relates one case which was cured by repeatedappings and pressure, but states in other cases these measures failed and death ensued. He also says, "We must regard all attempts to cure the disorder by making any kind of opening as exceedingly perilous, and generally fatal." Bryant writes in doubt. He says, "Almost all these cases prove fatal. Many of the subjects are ill-developed, and die within a few days of birth; some die in convulsions, and this mode of death is very usual when the sac bursts and its fluid contents escape." Then, as to treatment, he goes on to say: "Palliative treatment is all that can be followed in the majority of cases, although in exceptional instances operative interference promises to be of use." Holmes somewhat favors injection of the cyst, but this practice is almost only adapted to small pedunculated cases. Erichsen relates a case with an enormously large base, which was successfully treated by tapping. Probably the case he relates has no parallel in surgical literature; but he concludes, "We shall probably best consult the welfare of the child by abstaining from all operative interference." He does not even allude to injection.

The cases related at the Clinical Society, and the consequent discussion, prompt the inference that surgeons are at present most disposed to rely upon injection of the cyst. Still, the meagre success and the paucity of cases so treated scarcely justify reliance upon that method. Here is a void which surgical science requires to deal with without delay.

Three years ago, being on a visit in Worcestershire, I was requested to see the child of a farm laborer living in the adjacent village. The child, well nourished and healthy-looking, was six weeks old, and was the subject of a spina bifida, situated between the fourth and fifth lumbar vertebræ. It was the size of a small hen's egg. Mr. Woodward, of Pershore, had attended the case, and was present at the time I saw it. The skin looked shiny and red, and appeared ready to give way. I advised aspiration or tapping, and the latter procedure was adopted by a large hypodermic syringe needle, which was left in the sac for a few hours to drain. About eight drachms of fluid were withdrawn. A compress of cotton-wool was applied to protect the part, and the mother was cautioned not to handle the child roughly, and to avoid undue pressure on the swelling.

By the courtesy of Mr. Woodward, in August last I had an opportunity afforded me of seeing the child again. My notes of its condition, taken at

the time, run as follows. The child is fairly well nourished, and is about the height and weight of a three-year-old child, and has the appearance of full health. It can walk, but its gait is a little hesitating and slightly "straddling," with its feet rather more apart than natural, as though it had a difficulty to secure its equilibrium; the lower extremities are thin, but by no means emaciated, and sensation is perfect, the patellar reflex being intact, and plantar titillation immediately evokes the usual muscular jerk. There is perfect control over the sphincters, and the urine is voided in a full stream. There is no lack of intelligence, the eyes are full of expression, the head of normal size and shape, with no sign of hydrocephalus. Pressure on the tumour produces no symptom of distress, nor does it alter materially the size or shape. It has a very broad base, and the edges of the spinal aperture can be felt, the finger-tip detecting a large irregular ovoid opening communicating with the spinal cavity. The size of its base indicates its non-pedunculated character. The measurement in circumference at base is seventeen inches, and across from side to side eleven inches. It is as transparent as a hydrocele. The case, when first seen, did not encourage the idea of attempting a cure by injection, and I may mention that it has been tapped frequently, but has rapidly refilled each time.

The curious and interesting points about this case of hydrorachis seem to me to be these: the size of the sac; the full development of the lower extremities; the power of progression; the absence of pressure on the spinal cord, and thus the sphincter integrity. While the size of the opening would point to the possible pressure on the cord. If broad based tumours are more likely to press upon the cord than pedunculated ones, how is it there is no evidence of pressure here? Suppose the nerve structures are carried forward in front of the fluid, I think we might reasonably on physiological grounds expect to find evidence of nerve pressure, or malnutrition from nerve stretching, or from nerve atrophy. There is no talipes in this case. We are told not to puncture the front part of these tumours so as not to injure the nerves. But is there any evidence that the puncture of nerve structure in this part of the body by a fine needle has been productive of permanent mischief? This case seems to me, if not unique, at least curious, and prompts the following considerations. If the subarachnoid fluid both of the brain and spinal canal normally does not exceed two ounces, how is it that this tumour is so large? We know the fluid is reproduced rapidly when withdrawn, and the withdrawal when complete produces symptoms analogous to plethora of the bloodvessels, and when it is in excess it also produces convulsions and other evidences of pressure. There being direct communication between the spinal subarachnoid channel, and the cerebral ventricles, how it that when the fluid was all drawn away in this case no convulsions ensued? and this procedure has been observed several times without mishap. Does this part of the enveloping sac membrane from its large area alone secrete the fluid, or does the whole arachnoidal surface contribute its proportion? and if so why in such excess above normality? The question may also be prompted, Why is there usually talipes in these cases? Is that condition purely accidental or is it due to defective tissue growth dependent upon the spinal abnormality cutting off nerve-supply to a given set of muscles? I confess my inability to suggest any better method of treating, radically, hydrorachis; but, except in the matter of injection, we have made no advance in our knowledge of it during the last fifty years. This

is a reproach to our modern surgery, which boasts, and with perfect justice, of feats so brilliant that they become almost incredible as compared with the surgery of the past half century. Of this I am quite convinced, that something will dawn upon the intellect, as a more certain and effective means of dealing with this disease. An interest has sprung up which will eventuate in some satisfactory operation. Can we in any way imitate sloughing which produces spontaneous cure? To say that hydrorachis is an incurable disease would be considered unsurgical, but I am by no means convinced that some better method may not yet be discovered than we at present adopt. The old plan of a seton must be condemned, so I think must tapping and pressure, experience teaching that no reliable good ensues from these measures. It is to be hoped every successful case of cure by injection, no matter what the agent used may be, will be published, so that tabulated results may lay the foundation of something like a sound basis whereon to act, and which will inspire confidence in dealing with this *bête noire* of surgery.

Southport.

A CASE OF ANEURISM OF THE AORTA RUPTURING INTO THE PERICARDIUM.

By H. C. GUINNESS, Surgeon-Major, A.M.D.,

In Medical Charge, Station Hospital, Western Heights, Dover.

CORPORAL A. D—, Royal Irish Rifles (83rd), age twenty-three, service five years (no history of syphilis, alcoholism, or rheumatism), was admitted into Station Hospital, Western Heights, Dover, on October 24th last, with inflammation of external meatus. In spite of the treatment employed the pus became very fetid, showing its neighborhood to bone, and there was considerable constitutional disturbance with high temperature, etc. He became low and weak, requiring stimulants, etc., but no delirium or head symptoms occurred. During his life he had no symptom to direct attention to the heart or great vessels, and there was no suspicion of the existence of an aneurism. On November 12th, about 2 P.M., after his ear was syringed, he fell back in bed and expired almost immediately. As will be seen by the post-mortem report, the case is one of exceptional interest, owing to the mischief caused by the aural inflammation, the plugging of the lateral sinus and jugular vein, and the probability of this being the cause of the rupture of the aneurism by the increased pressure on its coats, also by the very small size of the aneurism. The post-mortem report I send in full, as furnished by Surgeon Skinner, Army Medical Department.

Necropsy.—Body pale and emaciated, rigor mortis well marked. On removing the skull-cap, the dura mater was found to be unusually adherent to the structures beneath, just above the torcular herophilli. The left lateral, petrosal, and cavernous sinuses were filled with ante-mortem clot; also the jugular vein in the jugular fossa, and for about an inch below that point. The brain substance was firm, but presented nothing unusual on examination beyond general emptiness of the veins. The left auditory meatus contained pus; it communicated with the jugular fossa by a perforation. On opening the chest, the pericardium was observed to be distended to its fullest extent by a dark substance. On opening it, some reddish fluid—in amount about two ounces—escaped, and the heart was found surrounded by a firm dark-colored clot, which on removal weighed ten ounces. This clot was found to be especially adherent to

the anterior surface of the first portion of the aorta; on removing it from this situation, a small aneurism was found rather larger than a hazel nut, with a perforation in its centre admitting a medium-sized bristle. The heart had a considerable quantity of fat externally and was firmly contracted. Its muscular structure was pale on section. The valves were healthy, but all the orifices were rather small. The aorta presented commencing atheroma in small quantity throughout its whole thoracic portion. The mouth of the aneurism was small, with a ragged margin, and blood-stained for about one-eighth of an inch round; it was a quarter of an inch in its transverse, and a little more than one-eighth of an inch in its vertical measurement. The aneurism contained some laminated fibrinous clot. The external coat was thickened in this situation, except just at the point of perforation, which, from the inner aspect, presented a funneled appearance. The lungs were collapsed and somewhat congested, especially at the base of the left. The liver was slightly enlarged and congested. The kidneys were apparently normal, also the spleen.

Remarks.—The post-mortem appearances suggest the opinion that the rupture of the aneurism was immediately due to the increased pressure caused by the blocking of the veins on the left side of the brain.

ON MANGANESE IN THE TREATMENT OF AMENORRHOEA.

By SYDNEY RINGER, M.D., F.R.C.P.,

Lecturer on Medicine in University College, Physician to University College Hospital;

AND

WILLIAM MURRELL, M.D., M.R.C.P.,

Lecturer on Materia Medica at the Westminster Hospital, Physician to the North-West London Hospital.

We are desirous of calling attention to the value of a very simple remedy in a very common complaint. For some time past we have used permanganate of potash with much success in the treatment of certain forms of amenorrhoea, and are satisfied of its value. Our observations have extended over a period of thirteen months, and we have now notes of sixty-nine cases. The majority occurred in hospital practice, but some were private patients. A small number remained under observation for a few weeks only, but the majority continued to attend for a much longer period; so that in some instances we have a complete record of the menstrual history for a year or more. In some cases the amenorrhoea was the cause of the patient seeking advice; in others its existence was mentioned incidentally, the patient suffering from some other complaint. Our cases are such as come under the care of the general as distinguished from the obstetric physician, and do not include those requiring operative interference. As a rule we refrained from making a vaginal examination, but with this exception our notes are complete. We have used the permanganate in two forms, first the pharmacopoeial solution, and secondly the permanganate made into pills, each containing either one or two grains. Generally we begin with a grain three times, and then gradually increase the dose to two grains four times a day. Our most striking results have been obtained with the larger doses; a large dose sometimes succeeding admirably after the failure of a small one. Before commencing treatment we inquire carefully into the menstrual history of the patient, and as a rule give the remedy only for the three or four days im-

mediately preceding the expected period, but should it fail to produce the desired effect we direct the patient to continue steadily taking it, and in some cases it has been taken continuously for nearly three months. In our experimental observations we have given the one drug only and have done nothing in the way of accessory treatment. Our most striking results have been obtained in young women between the ages of eighteen and twenty-five, who, from some accidental or trivial cause, such as catching cold or getting wet, have "missed" once or twice after having been regular. The administration of one or two grains of permanganate of potash in pill three or four times a day for a few days before the time of the expected period will bring on the flow almost to a certainty. In some instances the periods were brought on after the patient had ceased menstruating for over a year. In the case of country girls who have "seen nothing" for a month or two after coming to town the treatment has answered admirably. Often enough patients do not consult their doctor until they are "overdue," until the time of the expected period has passed by for some days. Even then the prompt administration of the permanganate will often bring on the flow at once, but should it fail to do so the treatment ought to be continued, and the patient will probably menstruate normally at the next monthly time. Generally our efforts are not crowned with success until the medicine has been taken for at least three or four days, but in some instances the permanganate acted with striking rapidity, the menstrual flow making its appearance after only two or three doses had been taken. It is not necessary to discontinue the treatment on the appearance of the menses; in fact we generally tell the patient to continue taking the pills three or four days longer, finding that it facilitates the flow. The permanganate often succeeds well after the failure of other remedies, such as iron, aloes, nux vomica, strychnia, pulsatilla, nitro-glycerine, and hot mustard baths. Sometimes, however, it is necessary to give it for six weeks or even longer before the desired result is obtained. In those cases where the patient has menstruated only once or twice, and has then entirely ceased for some months, our treatment answers well; the menstrual function is re-established, and thenceforth proceeds normally at every successive monthly period. In some cases there was no actual amenorrhoea, but the flow was scanty, lasting perhaps only a single day, or it may be only a few hours. Here the administration of the permanganate prolonged the flow, and even in some instances when it had ceased brought it on again.

In girls of about fifteen or sixteen, who have never menstruated at all, the permanganate, as might be expected, is not so certain in its action; but even here it not infrequently acts promptly, bringing on the flow at once. In some cases where the general health was bad, and the permanganate had failed, we suspended treatment for a time, and sent the patients into the country for a month. On their return we gave the permanganate a second trial, and it succeeded at once. We have, however, sometimes failed to bring on the menstrual flow even when the patient was in fairly good health, and when there were the usual indications of puberty.

It is not only in the case of young women that manganese is so useful; it succeeds almost equally well with women between thirty-five and forty, who, as the result of many pregnancies and much suckling, have ceased to be regular. Here, for example, is a typical case. A married woman came to us complaining that she was never regular. She had had nine children in as many years, and

rarely saw anything more than once between her pregnancies. She had been suckling for eight months, and had not been poorly for seventeen months—the nine months she had carried and the eight months she had suckled. She was not in the family-way, but said she expected she would be soon if she weaned the baby. She did not know when she ought to be poorly, and had given up all expectation of seeing anything. She was ordered two one-grain permanganate of potash pills four times a day, and came on poorly a fortnight after, the first time for seventeen months.

We need hardly say that before treating the amenorrhœa care should be taken to see that the patient is not pregnant, although we are satisfied that the permanganate given in the dose we recommend has no power to produce abortion either in the early or late stages of pregnancy. We find that manganese fails to induce the flow when the amenorrhœa is due to advanced phthisis. But in some cases of arrested phthisis the treatment was successful, and the patient, after a time, under the influence of the permanganate, menstruated freely and at regular intervals. In several instances patients informed us that the pills had proved of value in curing "whites" of long standing. As a rule the permanganate is taken without difficulty, but patients much prefer the pills to the solution. The solution is peculiarly disagreeable to take, and in some cases produces nausea and even vomiting. Patients frequently complained after taking the pills of a heavy persistent pain over the upper part of the sternum, "as if something had stuck there and would not go down." This was not due to the drug being given in the form of a pill, for the same complaint was made when the same dose was given in solution. One patient said the pain was of a burning character, and another said it was like heartburn. A girl of sixteen, to whom two two-grain permanganate of potash pills were given four times a day, said the pain, "like a lump at the chest," came on immediately after each dose, and was so intense that she had to go to bed for two hours.

That the effects we have described are due to the manganese, and not to the potash in the salt, is shown by the fact that manganate of soda and binocide of manganese are equally efficacious in the treatment of amenorrhœa. The manganate of soda was given in two-grain pills, two four times a day; and the binocide in four-grain pills, one four times a day. It may be thought that the manganese acts by improving the condition of the blood, but this is not the case. The treatment succeeds equally well in the plethoric and in the anæmic. Given in cases of chlorosis, the permanganate not infrequently brings on the period without in any way improving the anæmia.

A CASE OF ADDISON'S DISEASE,

WITHOUT TUBERCULOSIS OF THE SUPRA-RENAL BODIES
AND WITHOUT AFFECTION OF THE SEMILUNAR
GANGLIA.

By R. G. HEBB, M.A., M.D. Cantab.,

Pathologist and Curator of the Museum at the Westminster
Hospital.

THE present pathology of Addison's disease assigns its cause to be a "tubercular destruction of the supra-renal bodies," associated with "a general pigmentary deposition in the rete mucosum, and a remarkable form of progressive asthenia, which sooner or later ends in death." A similar explanation is given by Drs. Wilks and Moxon in

their "Pathological Anatomy," but here more stress is laid upon the connection of the caseous degeneration of the adrenals with tuberculous disease of the lungs. Again, Dr. Greenhow, in his monograph on Addison's Disease, p. 25, where he is discussing the morbid process which takes place in the supra-renal capsules, lays it down that it is always identical, and "consists primarily in their infiltration by an inflammatory exudation of low type, which destroys the normal structure of the organs, and finally itself undergoes caseous degeneration." And in his paper on Addison's disease read before the International Medical Congress, 1881, he refers "most of the more prominent symptoms of the disease to some morbid condition of the neighboring nerves," and further states that "it is almost certain that these symptoms are caused not by impairment of any special function of the supra-renal capsules themselves, but by injury to the important branches of nerves which pass into the capsules, and of the ganglia and plexuses in their immediate neighborhood." Hence it would seem that while some pathologists conceive that the inflammatory lesion suffices to develop the symptoms, others believe that, though the tubercular condition is always present, the symptoms are due to some affection of the neighboring nerves and ganglia. Yet the following case tends to show that, on the one hand, tuberculosis of the supra-renal bodies is not required to cause Addison's disease, and, on the other, that the symptoms of this malady may exist without any apparent lesion of the adjacent sympathetic ganglia. The case is especially noteworthy, because of (1) the complete absence of caseation and of tuberculosis; (2) the atrophic condition of the supra-renal bodies; (3) the correspondence of the smaller supra-renal body to the larger ganglion. And, I conclude, from a consideration of the morbid appearances, that the pathological element of this disease is to be sought in the central part of the supra-renal capsules themselves.

Mary A. C—, aged forty-eight, was admitted into the Westminster Hospital under the care of Dr. Fincham on March 31st, 1882. Her father's brother suffered from gout, one of her sisters died of phthisis. The patient is a married woman, and has had eight children. The menopause took place four years ago. She has had no previous bodily illness, but in 1880 had some great domestic trouble; has not suffered from exposure, privation, or injury. For the past year she has been complaining of weakness and has become much worse in the course of the last three months, during which period she has been losing flesh. Six weeks ago she began to suffer from headache, which has continued ever since. The darkness of the skin commenced to show itself about four weeks ago, or at least was not noticed before. The above symptoms became intensified in the beginning of March, and were accompanied by fainting fits, constipation, and nausea. During the two weeks previous to her admission the loss of strength and flesh was very rapid. She then began to vomit her food, and has retained very little nourishment ever since. The patient has been laid up in bed for one month. On admission it was found that she was very weak, and somewhat emaciated, with an anxious, drawn expression and sunken eyes. There was a general duskeness of tint over the face and the whole surface of the body. On the back and right side of the neck, and on both elbows, were a number of circular dark-brown patches; the areolæ were of a dark-chocolate color, and on the mucous membrane of the left cheek was an irregular dark patch about the size of a six-penny-piece. The pulse was small and weak, and the heart's action rapid but regular. There were

¹ Bristowe's Medicine, Fourth Edition.

no abnormal auscultatory signs in the thorax. Urine acid, sp. gr. 1020; no albumen. Weight 6 st. 12 lb. 10 oz. Patient constantly vomited. She was ordered liquor arsenicalis, five minims, after food. Between this and her death the patient vomited all nourishment taken by the mouth, and peptonized food was administered per rectum. She became rapidly weaker, and died April 7th. Her weight taken a few hours before death was 6 st. 3 lb. 10 oz.

Necropsy made by Dr. HERR, nine hours after death.—Body somewhat emaciated, but there was a considerable amount of adipose tissue within the abdominal cavity; slight rigor mortis; the viscera were quite warm; there was a subconjunctival hæmorrhage of the left eye. The blood was quite fluid, and contained an unusual quantity of free liquid fat. There was no staining by blood coloring matter of the serous or other tissues. There was not a trace of caseation in any part of the body. The skin generally was bronzed, but there were patches of deeper pigmentation in the following situations; around the nipples, in both armpits, in Scarpa's triangles, below both knees, over against the lower cervical region an irregularly oval area about six inches by four inches, and on the mucous membrane of the mouth and of the vulva. Brain weighed 50 oz.; membranes and nervous tissue normal. The pleuræ were quite smooth and shining. Both lungs were crepitant throughout. Heart weighed 6½ oz., the valves were competent; the aortic measured 2.75 in., the mitral 3.50 in.; the muscular tissue was firm but of a brownish color. The pericardium was normal. The liver weighed 50 oz., normal. Spleen 2½ oz., soft. Kidneys each 4½ oz., congested, otherwise normal. The supra-renal bodies weighed—right, 28 gr.; left, 19 gr.; they retained their shape, were of a reddish color, and of a softer consistence than usual; on section the internal pearly-white layer was found to be absent. The abdominal sympathetic ganglia, especially the left semilunar ganglion, seemed larger than usual. The stomach contained several ounces of a pul-taceous material of a malachite-green color. Both ovaries were shrunken, and from the os uteri poured a glairy white discharge, otherwise these viscera were normal.

Microscopical examination of the semilunar ganglia failed to discover any lesion of the sympathetic nerve cells, although comparison with several normal semilunar ganglia suggested that there might be increase of the connective tissue element. The bloodvessels were certainly larger and more numerous.

Torrington-square, W. C.

MEMBRANOUS POLYPUS OF THE CERVIX UTERI.

By CHARLES GIBSON, M.D.,

Lecturer on the Diseases of Women, etc., in the University of Durham College of Medicine, Newcastle-on-Tyne; Consulting Physician to the Newcastle Dispensary, etc.

In the body of the uterus there are principally two forms of benign polypus found—viz., the soft or mucous, and the fibrous or muscular, which may be regarded as an extension of the proper tissue of the uterus, covered by a corresponding extension of the lining membrane of the organ. In the neck of the uterus one other well-recognized form is superadded—viz., the glandular, principally constituted by enlarged glands of Naboth. In addition to these, however, several varieties are recognized: the fibrinous, either from a coagulum in utero, or from an aborted ovum; the

vascular, from varicosity of the submucous blood-vessels; the placental, which again results from detained and variously altered placenta; the fatty polypus may be regarded as a degenerated fibroid.

The polypus of which this paper takes special cognizance does not belong to any of these varieties. Yet it is strictly a benign polypus, springing from the internal surface of the cervix uteri. Some years ago I saw a patient who had been out of health for many months. Her age was about fifty. She was stout, but there was a sustained feeling of indisposition in the patient, and exertion with her soon produced fatigue. This lady was keenly susceptible to the influence of cold, and when acted upon by it, she commonly became affected with cervical uterine leucorrhœa. When this patient came under observation there was present aching of the lower part of the back, around the hips, and down the thighs; but there was no other localized complaint, excepting only slight tenesmus on defecation and micturition. The grand climacteric had been passed, but the later catamenial periods were marked by much discomfort, even by suffering, and by great irregularity in the character and in the quantity of the discharge. On examining the uterus per vaginam with the finger, the os uteri was found to be much dilated, and immediately within it a rounded body was reached by the examining finger. The cervical walls were soft and even. No blood issued on feely touching the intra-cervical foreign body. By the aid of the vaginal speculum the presenting tumour was seen to be evenly rounded in outline, and to fill completely the canal of the cervix uteri. Nothing like blood or pus covered it. On pressing the uterine probe upon this dark-colored body it became deeply indented, and by onward pressure it receded within the cervical canal. On withdrawing the probe the tumour resumed its former site and appearance. Laminaria tents were passed through the cervical canal, and free dilation of it was effected. And now, on making digital and ocular examination, the tumour was nowhere to be found, and no bearing down on the part of the patient and no pressure on the hypogastrium could force the growth again into view. The finger, indeed, could feel an uneven condition of the anterior wall of the cervical canal, but no other abnormality could be detected. The cervix was allowed to contract upon itself again, and on the fourth day after the examination just referred to the tumour was again found in the cervical canal. It was now carefully examined and found to have a broad attachment to the anterior cervical wall, and to be gradually lost in the surrounding parts. Excepting for the points of attachment the tumour did not appear to have, exactly, any of the characters of the polypus formed by enlarged Nabothian gland. It was concluded then that the abnormal growth was nothing but a rounded fold—a prolapse, in fact—of hypertrophied cervical mucous membrane. On this assumption a line of treatment was determined upon and carried out. The wall of the cervical canal, after dilatation, was freely swabbed with the stronger solution of perchloride of iron; and a dossil of lint, saturated with glycerine, was placed in the canal for twenty-four hours. This operation was repeated on three other occasions, after which neither probe nor finger could find a vestige of the tumour. On seeing this patient three weeks after the last application the cervical canal was found to be free from abnormal growths, and the discomfort and tenesmus formerly felt had quite disappeared.

About two years ago this patient again came under my observation with symptoms nearly identical with those already referred to. Some persistent leucorrhœa, however, was superadded.

On examination a tumour was found similar in many particulars to that which had been observed before. It was, however, much larger, and hung down from the uterine orifice into the vagina. It had the form of a pear, and was attached by its pedicle to the anterior wall of the cervix uteri. The growth was now summarily dealt with: a loop of fine wire, passed through a silver tube, was carried over the polypus, as nearly as possible to the points of its attachment to the cervical wall, and tightened; then, with a seesaw motion of the wire the attaching textures were cut through, and the tumour was removed. Although there was almost no bleeding, the stronger solution of perchloride of iron was freely applied to the cut surface as a matter of security. In two days the patient was well, and has continued so up to the present time. On examination of the tumour after maceration in a solution of common salt, it was found to be pear-shaped, as before removal, its walls enclosed, and were held together by a tolerably firm connective tissue, and yet by manipulation the envelope could be flattened out, a nodule only of the connective tissue, more dense than the rest, remaining on the surface of the envelope after the other portions had been unfolded.

In another case of like nature, the tumour was small but easily recognized, the cervical canal being large and the uterus itself very low in position. The patient was still menstruating, the periodic discharges, however, being long continued each time, and very profuse. In this case the stronger solution of perchloride of iron was repeatedly applied to the abnormal growth, and to the circumjacent mucous membrane. These applications were followed by the introduction of an intra-uterine stem pessary, and vaginal injections of cold water were employed. The pessary was worn for some months. The result of this treatment was entirely satisfactory.

This affection is produced, I think, by engorgement of the mucous membrane of the cervix uteri. It clearly has no connection with the dilatations and contractions of the cervix which belong to parturition, neither of the patients referred to having borne children. The mucous membrane, however, becomes relaxed by recurring catamenial plethora. The relaxed membrane folds upon itself, tenesmus is thence set up, as upon a foreign body in the cervical canal, and the loosened membrane is gradually forced downward. Then exalted nutrition of the mucous membrane and of the sub-mucous connective tissue follows upon the recurring plethora. The hypertrophied textures offend more and more as their growth increases, and the polypoid character of the tumour, as it extends beyond the uterine orifice, becomes marked more and more distinctly.

The literature of uterine affections does not present, so far as I am familiar with it, any well-marked cases of the kind now delineated. Doubtless such cases have often occurred before, and will often occur again. It is highly desirable, therefore, that these morbid outgrowths shall henceforward be recognized by gynecologists, and their etiology and pathology securely established.

NOTE ON AMPUTATION.

By WM. S. SAVORY, F.R.S.,
Surgeon to St. Bartholomew's Hospital.

PERHAPS in no case is the judgment of the surgeon more severely taxed than when he is called on to decide the question of amputation in an injury to a limb. The rules of surgery on this subject are necessarily very vague, and too often they

can be applied with but little force to the particular instance; for in any case, many considerations, each one largely affected by the rest, are involved. Of course when the injury is of such a nature, from the destruction of large vessels, nerves, or other important structures, that recovery is out of the question, there is no room for doubt. It is when the injury is of such degree and extent that although recovery is possible, it is yet improbable, involving very grave risks to life, that the surgeon's anxiety is raised and his way becomes difficult. Often in these cases one man forms a decided opinion on what appear to others to be very inadequate grounds. Even when to others his conclusion appears to be sound, he may fail in explanation to set forth sufficient evidence of it. If he has really reasoned on the subject, he cannot reproduce the argument for the guidance of another. He gets no farther than, "I think upon the whole," etc. He may be right, as right as a man who can express his thoughts and explain clearly the ground of his opinion; but it must be allowed that this kind of decision is neither instructive nor satisfactory.

In endeavoring to form a judgment in such cases it seems to me that one has to consider, first of all, whether the injury is greater than any operation for its removal. If the operation would not be the means of substituting a less injury for a greater—less for more risk in the future—it surely ought not at this time to be thought of. And deciding in favor of an operation on this ground, the question comes, Is the chance of recovery from the operation so much greater as to cover the risk from the second shock which the operation would necessarily cause? This last consideration oftentimes adds greatly to the difficulty of decision. Then further, assuming the injury not to be beyond all reasonable chance of repair, is it worth while, for the prospect of such future use in the limb that might remain to him, for a man to run, in order to preserve it, any additional risk of his life? and, if so, to what extent? With all this it has to be borne in mind that if an attempt is made to save the limb, in the event of failure there may be some chance in the future of removing it, and of still saving life. But the probability is that such secondary amputation will be forced on us under unfavorable conditions; in other words, that there will be but little choice of time.

The opinion of surgeons has of late years gradually changed respecting the comparative advantages and disadvantages of what is called primary and secondary amputation after injury. It was formerly held that less risk to life is incurred by operating immediately after an injury than at a remote period, and this view was, I believe, founded chiefly on the records of military surgery. This, however, has not been confirmed in recent years by the experience of civil practice, and I suppose that at the present time such a question would receive for the most part doubtful or contradictory answers. Does not this depend on the want of distinction which ought to be drawn between different cases of secondary amputation? When in an instance of severe injury an attempt is made to save a limb much local and some constitutional disturbance is sure to follow, and in unsuccessful cases the patient either dies directly from this, or the limb passes into a condition beyond prospect of recovery. Now, in the question of secondary amputation, if we can select our own time for the operation, when the fever or constitutional disturbance which has been provoked has subsided, and we operate to remove a useless or hopelessly damaged limb, such amputations are done, I believe, with better prospect of success than primary ones, and this chiefly because they remove a

source of great and perpetual irritation with comparatively little shock. But if, while much constitutional disturbance prevails, we are called on to choose between amputation and death, we operate under most adverse circumstances and with much greater risk, no doubt, than in primary amputation.

So, then, I should answer the question thus: Secondary amputations are more favorable than primary ones when there is a choice of time—that is, when we can afford to wait till the temperature and other signs of general disturbance have subsided; but secondary are less favorable than primary amputations if the operation is forced upon us at a period of the case when a high degree of fever still prevails. Herein, too, lies the difference in the prospect between secondary amputation after injury and amputation in disease, for in the latter case there is almost always choice of time.

FIBRINOUS COAGULA IN THE HEART AND PULMONARY ARTERY.

By SIR JOSEPH FAYRE, M.D., F.R.S.

MANY years ago, when in India, I called attention to the subject of thrombosis of the pulmonary artery, and the formation of decolorized fibrinous clots in the right cavities of the heart, extending into the ramifications of the pulmonary artery, as a cause of death after surgical operations or injuries, and also during the course of blood-poisoning and certain forms of disease. My views and experience in this subject are detailed in a work entitled "Pathological Observations in India," and I now revert to it as a subject which merits more consideration than it has hitherto received and is entitled to, as a serious and often fatal complication of cases, which otherwise might have terminated more favorably.

These decolorized fibrinous clots in the heart and pulmonary arteries have been attributed either to post-mortem coagulation or, when admitted to be of ante-mortem occurrence, they have been considered as merely one of several phenomena which attend the process of dying, and not as an immediate cause of death. This, I venture to contend, is not always the case; but, on the contrary, that such clot and plugging of the pulmonary artery or the right cavities themselves cause death not unfrequently in cases in which without them death could not have occurred. My experience of this subject has been acquired chiefly in India; but it has been confirmed by observation in this country, and I am under the impression that this is a more frequent cause of death, not only in the course of pyæmia, septicæmia, and certain diseases, but also after surgical operations, wounds, and injuries.

A malarious climate I believe to be an especially predisposing cause, and in the state of malarial cachexia which so frequently results from residence in such countries, even where there may have been no fever, and especially in cases where anæmia is splenic or hepatic incompetency is present, it is prone to happen. But it is by no means confined to persons so affected, for I have frequently seen it in individuals who presented no cachectic appearance nor in whom was there any obvious indication of visceral disease. Obstruction of the pulmonary artery and right cavities of the heart by coagula, causing death, may thus occur in persons not cachectic from malarial influences. Still, the disease is especially liable to affect persons laboring under that impaired state of

health; where the spleen is diseased it is very prone to happen and to prove rapidly fatal.

Hyperinosis, or excessive formation of fibrinous material in the blood, is the condition on which the thrombosis depends, whilst the condition which occurs in surgical fever, pyæmia, and in exhaustive diseases such as cholera, malarial fever and cachexia, diphtheria, scarlatina, puerperal and other diseases, leads to the hyperinosis. Thrombosis of the pulmonary artery kills by arresting the passage of blood through the lungs, whilst coagula in the left side of the heart and thrombosis of the arteries operate locally by causing gangrene of the part. There is, however, a strict analogy between the two forms of thrombosis; they arise from fibrinous material in the blood, and the predisposition to the formation of this is equally engendered by exposure to malarious influences, as it probably is by other diseased states.

The so-called abscesses which are so frequently found disseminated in the tissue of the liver, spleen, kidneys, lungs, and in the areolar tissue in persons who live in hot and malarial countries, are not primary abscesses, but originate in patches of parenchyma which have perished owing to the deposit of emboli in the small vessels at the spot. Around such dead patches, as around the core of a boil, pus is subsequently found, and so the local death is converted into an abscess; though in cases of blood-poisoning in India death frequently occurred before these suppurations took place, when the part was found simply as a piece of dead tissue surrounded by an areola of congestion or inflammation.

As to the mode in which the change in the blood is brought about I am ignorant, though it is not difficult to understand why it should be so when the spleen and other blood-elaborating organs are compromised. But of the fact and of its consequences I know there can be little doubt, as many cases within my own observation have convinced me. This subject has been recently attracting attention, hence these remarks, derived chiefly from experience in India, but probably applicable here.

Some of the most remarkable examples of this morbid condition have occurred as sequels, if not direct results, of injuries, wounds, or surgical operations, not only in cases where pyæmia had supervened, but in others, in which nothing indicated the approach of danger until the symptoms of obstructed pulmonic circulation had set in. It is my belief that climatic influences, by deteriorating the blood-elaborating organs and by interfering with the due action of the trophic and vaso-motor apparatus, may determine the occurrence of changes in the blood which render it prone to the formation of these coagula, and in climates like that of Bengal, where all are more or less exposed to malarial influences, its greater frequency than elsewhere may be thus accounted for. But thrombosis of the pulmonary artery and cardiac clot are neither confined to malarial climates nor to traumatic causes, for under certain conditions of disease and of septicæmia, whether traumatic or otherwise, it may occur everywhere, and not merely as a process of the act of dissolution, but as an independent cause of danger or death which, without it, would not have happened.

I am aware that Dr. Richardson and others have long ago pointed out the tendency of the blood to assume this dangerous condition in certain diseases; but it is to the analogous condition when determined by malarial and splenic cachexia or by other conditions which induce leucocythæmia, and to that which results from wounds, injuries, and operations (traumatism), that I now refer, and of which I express my belief that it is a more fre-

quent cause of death than is generally supposed, especially after wounds, operations, or injuries which involve removal of large parts of the body, or much loss of blood and great nervous disturbance; and I would, with much deference, suggest that some of the deaths which have been ascribed to what appear insufficient explanations may have been due to this cause.

Thirteen or fourteen years ago I wrote as follows in regard to a case where death had resulted from this cause after a comparatively trivial injury, a contusion, which had caused sloughing of a small portion of integument on the leg: "There was not sufficient in this case to account for death in an ordinary individual, but in a person suffering as he did from malarial poisoning and enlargement of the spleen, it was more than sufficient. Probably in no condition of disease is the formation of fibrinous coagula more likely to occur on the least disturbance than in splenic or malarial cachexia, in which the deteriorated condition of the blood-elaborating organs and the impoverished character of the blood are proved by the anæmia, and the tendency to disintegration and death of the tissues which is so often seen. The evil results of the hyperinosis are seen in the limbs or other parts of the body, which become gangrenous from embolism when it is in the arterial circulation, and cedematous or gangrenous when it occurs in the venous system; or, still worse, in the multiple deaths of portions of the viscera, which are so frequently observed after wounds or injuries.

But it is the formation of the fibrinous clots in the cardiac cavities themselves, and particularly on the pulmonic side of the circulation, which is so dangerous to life. I have repeatedly called attention to the subject as one of great importance, for it is not only in cases where an enlarged spleen renders almost any operation impossible, and which causes almost any wound to prove fatal, but in many others, whether of wound or injury, where there is no obvious disease of the spleen and no cachexia, and where all seemed to promise a favorable issue, that this condition may supervene and rapidly cause death. It is common enough in some diseases as one of the latest phenomena manifested by the moribund; but more than this, it may set in when there is no sign of exhaustion, when repair and nutrition are going on satisfactorily, and within a short time hurry off the patient, whose dead body presents no explanation of the cause of death beyond the presence of a firm, decolored, adherent clot in the right auricle or ventricle, perhaps extending into the ramification of, or it may be impacted in the entrance to, the pulmonary artery.

I have so far noticed the malady as it occurs in persons who are free from cardiac disease, but that it occurs in them is the more reason why it should happen to those in whom a fatty heart is superadded, especially in a hot, damp, and exhausting climate, or even when the heart, though not itself the subject of fatty degeneration, is loaded with fat, externally, or where there are dilatation weakened muscular cardiac fibre, and, perchance, pleuritic or pericardiac effusions. In such persons, indeed, the presence of fibrinous concretions may not be needed to determine a fatal issue. The temperature of a hot, damp night, in May or June (always the time of greatest vital depression), in Calcutta, and the shock or after-effects of an operation or the depression following an attack of malarial fever, may be sufficient, and the patient, after a short and painful struggle of breathlessness, perishes, notwithstanding every effort to save him. This is very distressing; especially when it occurs to a person who appeared to be recovering, and it becomes a subject of anxious inquiry not only as

to how it was caused, but how it may be prevented in others.

I propose to describe the symptoms of, and to illustrate them by, some typical cases in a future notice.

Wimpole-street, W.

BULLOUS ERUPTION OF A PECULIAR CHARACTER.

By RICHMOND LEIGH, M.R.C.S. Eng.,

Surgeon to the St. George's Hospital for Diseases of the Skin, Liverpool.

M. W—, aged thirty-three, very healthy, was affected by a peculiar eruption five days after parturition. It appeared as bullæ of irregular shape and size, varying from a quarter of an inch to about an inch in size. It was not preceded by redness, pain, or other sign or symptom. But for the absence of redness, the appearance was that of a blister, for which it was taken by a surgeon who saw the case early. As the bullæ burst, there was some slight rawness from the loss of epithelium, but not beyond the margin of the bullæ, and also some slight soreness and purulent discharge from the friction of the clothes, but no pain existed from other cause throughout the course of the disease. The height of the eruption was reached about three or four days from its commencement, and fresh bullæ appeared at intervals in its course for over a week. After the discharge of the contained fluid the bullæ dried up gradually with little reddening, rawness, or discharge, except where irritated by rubbing. Accompanying the eruption was an eczematous affection of the eyes and lips, which remained after the disappearance of the former. The trunk was the only part affected, and with the exception of a portion of the buttocks, only on the anterior aspect, which was irregularly covered by the eruption from the neck to the groins. The duration of the complaint was about fourteen days. It was probably of neurotic origin, the result of "cold," but no nerve region was specially marked out. There was no fever, and the general health was unaffected, except that there was some little debility more than usual. No history of syphilis was elicited, and the woman had had no abortions, or stillborn or premature children. She was married very early, soon after the age of fourteen, and had had eleven children before the present one. The milk appeared on the third day, without much febrile disturbance.

The treatment was general; iron and quinine on account of the debility, and vaseline locally.

Park-road, Liverpool.

PENETRATING WOUND OF THE ORBIT; BULLET LODGED IN THE BRAIN.

By A. EMBYS-JONES, M.D.,

Surgeon to the Royal Eye Hospital, Manchester.

ON Monday, Nov. 6th, I was summoned in a great hurry to see a case in consultation with my friend, Mr. W. Armstrong, of Harpurhey, who informed me that a boy, aged fourteen, a few hours previously had been handling a revolver, the contents of which had been discharged into the orbit, and most likely into the brain. The boy was evidently in pain, and it was deemed advisable to give him a few drops of chloroform before proceeding to make an examination; but just as he took the first few sniffs he struggled violently, and then fell into a state of collapse, and, in spite of all that could be done, he did not breathe again, al-

though the action of the heart kept up for some time.

On Nov. 8th we made a post-mortem examination, and found the following appearances:—The eyeball was extensively ruptured, and internally a large irregular opening, about half an inch in extent, at the junction of the ethmoid and sphenoid bones, and continuous with the opening a large hole extending through the cerebral convolutions to within an inch of the posterior boundary, where we found the bullet.

The track was filled with blood, and the débris of bone carried along with the bullet. There was extensive hæmorrhage into the adjacent parts and the ventricles. We found all the other organs healthy.

Manchester.

SUCCESSFUL EXTIRPATION OF THE LARYNX.

By WALTER WHITEHEAD, F.R.C.S.E., F.R.S. Edin.,

Surgeon to the Manchester Royal Infirmary.

LARYNGEAL surgery has of late attracted considerable attention, and as the profession is somewhat divided in opinion on the respective merits of extra and intralaryngeal operations in dealing with laryngeal growths, I wish to place on record the particulars of a case favorable to the former procedure.

W. G—, aged forty-six, blacksmith, was admitted into the Manchester Royal Infirmary on April 28th, 1882, on the recommendation of a medical friend, who suggested the desirability of removing a growth which he had discovered attached to the right vocal cord. The patient had suffered from extreme hoarseness, difficulty in breathing, distressing cough, and occasional paroxysms of dyspnoea, for three months before coming under observation. Laryngoscopic examination afforded a conjectural diagnosis that the growth, which overspread the right vocal cord, was of an epitheliomatous nature. The disease could only be inferred to extend beyond the range of vision by the knowledge that malignant neoplasms in that locality usually extend below the cords. Tracheotomy was performed as a preliminary measure on April 30th, the operation giving immediate, but only temporary, relief to the more pressing symptoms. A recurrence of ominous dyspnoea, which was afterwards discovered to have been produced by the imperfect manner in which the cannula had been reintroduced after having been removed for cleaning, hastened the decision to remove the disease.

On May 27th the thyroid cartilage was slit from below upwards and the two halves held apart, when it was seen that the new formation not only implicated the vocal cord, but extended, as was conjectured, downwards, and involved the upper part of the trachea. Before proceeding to excise the diseased structures, Trendelenburg's tampon was substituted for the tracheotomy cannula, and the insufficient protective influence of the tampon against blood finding its way down the air-passages was guarded against by packing the trachea above with a small sponge. The whole of the disease, the thyroid and cricoid cartilages, and the two upper rings of the trachea, were then removed by means of scissors. The epiglottis was left intact. The skin was brought together by a few silk sutures, and the wound dressed with dry lint.

On the following day Trendelenburg's tampon was replaced by a soft rubber tube which still remains *in situ*. A microscopic examination of the growth confirmed the diagnosis as to its being an epithelioma. The patient's voice was not immediately

lost; for several weeks after the operation he could express himself in monotone and could be distinctly heard at a distance of six feet; gradually the sound faded and eventually disappeared altogether. It can still be demonstrated, by means of a flame in front of the mouth, that air finds a channel in the track of the original air passages. The patient now breathes quite freely, takes his food without inconvenience, and enjoys life as fairly as can be expected under the circumstances. The absence of any local glandular enlargement or evidence of any recurrence of the disease affords a reasonable prospect that the patient may derive prolonged benefit from the operation. The idea of introducing the artificial vocal apparatus of either Gussenbauer or Foulis was entertained, but abandoned on the grounds that no real advantage had yet been established in favor of these instruments. The preference for thyrotomy was based on the opportunity it affords for a complete inspection of the entire larynx, and the facility it gives for extending or restricting the extent of the operation to any limit necessitated by the amount of the disease. The only difficulty met with during the operation was the separation of the deeper attachment.

Manchester.

ON VENESECTION.¹

By W. H. BROADBENT, M.D., F.R.C.P. Lond.,

Physician to St. Mary's Hospital, etc.

THE disuse of bloodletting as a remedy has so frequently been the subject of remark that observations respecting it, except by way of explanation, are unnecessary. We are often disposed to reproach ourselves when we contemplate the extreme and violent fluctuations which have taken place in the practice of medicine, both as regards the alternate employment and abandonment of particular drugs or lines of treatment, and as regards the principles of treatment generally; but while we have reason to be ashamed of the influence which mere fashion and love of novelty exercise, some of the changes which at first sight seem most inexcusable and unaccountable have really been the inevitable results of increasing knowledge and the steps of advancing science. I believe this will prove to have been the case with venesection. Bleeding was formerly employed with little discrimination; in some cases it did good, in others it must have done harm; in a still greater number it probably had no appreciable influence on the course of the disease, but did not injure the patient. The uselessness and danger of the practice were frequently shown, but doctrine or theory has with the mass of men far more influence than observation, and while the experience of one set of observers was simply set against that of another, recoveries without bleeding did not carry conviction to the minds of those who had seen recoveries after bleeding; and it was only when, by the evidence of the post-mortem room and the experimental study of inflammation and other morbid processes, a revolution in the general doctrines as to disease had been effected that the balance was turned, so that venesection was condemned and abandoned.

During some years there has been a gradual reaction. It has been shown, notably by Sir James Paget, that venesection is attended with very little risk either of immediate or remote injury, while on the other hand it is in suitable conditions a remedy of striking power. A return to indis-

¹ A paper read before the Harveian Society, Feb. 1880, with slight additions.

criminate bleeding would be a great evil, but of this there is really no danger. It is now better known what abstraction of blood can do and what it cannot. The indications for resorting to it can be more precisely defined, and sooner or later the teachings of physiology applied to the rectification of abnormal conditions present in disease will remove the stumbling-block for a time thrown in the way of this powerful therapeutic agency by morbid anatomy.

In the first place, general bleeding is not employed as a remedy for inflammation as such. We have in the writings of our predecessors a vivid description of the effects of venesection in *iritis*—the relief of pain, the diminution of vascularity, the arrest of destructive changes; but true as this undoubtedly is, such advantages, even were they constant, which is by no means the case, may be purchased too dearly, and there is no inflammation of an internal organ in which venesection is resorted to. Nor is it for the control of *pyrexia*, whether the result of a local inflammation or of one of the specific fevers. What we seek to do, and what we can effect by venesection, is to modify the distribution of the blood and the pressure within the arterial or venous system. The circumstances under which this may be required are various; some of them I shall enumerate, and, when I can do so, illustrate by recent experience of my own.

Perhaps the most simple and unmistakable indication for the necessity of reducing the blood-pressure within the arteries by bleeding is when an aneurism is giving rise to severe pain, or is threatening life by pressure upon a nerve or some important organ. I have repeatedly seen immediate and striking relief afforded by a small bleeding in the practice of the late Dr. Sibson, whose teaching and example I have followed. An opportunity occurred last year, when a patient, who had been some time under my care in St. Mary's Hospital suffering from a large aneurism of the arch of the aorta, was suddenly seized with violent dyspnoea during my visit to the wards. His face was purple and swollen, and he was evidently in agony, while it seemed as if he must die within a few minutes unless relief could be given. My resident medical officer, under my supervision, bled him to about eight ounces, and he was very soon in a comfortable sleep. In aneurism, however, bloodletting can only be palliative, and though it may relieve pain and prolong life for a time, it does not restore the sufferer to health. Much more than this is claimed for venesection in another class of cases, when it is practiced for the relief of over-distension of the right side of the heart. The circumstances under which this condition arises are various, but they are chiefly comprised under disease of the heart, or obstruction to the pulmonary circulation by disease of the lungs, especially pneumonia and bronchitis.

Pneumonia has been the great battle-ground of many therapeutic controversies, but especially of the question of bleeding and the use of stimulants. A more unsuitable field could not have been chosen. It is a disease which varies extremely as to the danger attending it at different times and places, and under different circumstances, quite irrespective of the treatment pursued, so that statistics are fallacious. Again, it runs a definite course and terminates by a very marked crisis, which allows an enthusiast or partisan to imagine that the remedy which coincides with the crisis has brought it about. The clinical history of pneumonia, uninfluenced by any but hygienic treatment, having been carefully followed and ascertained, it became possible to estimate the effects of bleeding, and it may be stated confidently that

in some cases it is most useful, preventing suffering and saving life, while in others it would only be injurious. The reason is that it is not the inflammation of the lung which is combated, but a particular complication—over-distension of the right side of the heart. The merit of making this clear and of enabling us to recognize the indication for bleeding in pneumonia is, I believe, due to Dr. Markham. In some cases, then, of pneumonia the rapid consolidation of a certain part of the lung with congestion of a still larger portion gives rise to a degree of obstruction in the pulmonary circulation which embarrasses the right ventricle; this no doubt, being enfeebled by the high temperature of the blood, induces dilatation, and eventually almost paralysis. The symptoms attending this condition, which may be established very early in the attack, are most distressing: the patient is pale or livid, instead of flushed, is gasping for breath, and probably unable to lie down; the *alae nasi* are working; he can scarcely speak, and the cough, if any be present, is a mere short hack, raising no expectoration; there may be a cold sweat on the face. On examining the heart, it is found to be beating violently, and a striking contrast is presented between the force of its impulse and the small and weak beat of the pulse, explained by the inadequate amount of blood which finds its way to the left ventricle, in consequence of the obstruction in the lungs and the enfeebled state of the right ventricle. However forcible the systole may be, it can have little effect on the pulse if there is only a scanty amount of blood in the ventricle to be driven into the arteries. The right auricle can generally be made out much beyond the right border of the sternum. It is under these circumstances that those striking effects of bleeding are obtained which have been so often described and which I have myself witnessed. As the blood flows the pulse improves, becomes fuller and stronger; the breathing becomes less frequent and shallow; the oppression is relieved; and not uncommonly the patient, finding to his astonishment that he can take a deep breath and cough without pain, expresses himself as feeling quite well. The pneumonia pursues its course under more favorably conditions, and recovery is usually the result. Cases of this kind are rare in the hospital practice of London, but I have met with a few. In the country they are more common.

Bronchitis frequently gives rise to over-distension of the right side of the heart, and I have seen venesection employed for its relief, but I have never ventured to practice it myself. In chronic bronchitis and emphysema, in which distension is always more or less present, the conditions which produced it persisting would certainly cause it to recur, and even acute capillary bronchitis is usually of such long duration that a single bleeding could not be looked upon as final. There are, however, no doubt cases in which we ought to give the patient the chance which venesection seems to offer in desperate circumstances, but I have hitherto preferred having recourse to an emetic, which will at the same time unload the air-passages and powerfully compress the heart, forcing the blood out of the right ventricle, and so far relieving the over-distension as to enable it to complete its systole, which is the end to be obtained.

In heart disease I have seen no case of aortic valvular affection, obstructive or regurgitant, in which venesection seemed to be called for, and in mitral regurgitation the good effects of digitalis can be relied upon with so much confidence that it claims the first trial. It is in mitral stenosis that bleeding is most frequently demanded. When the mitral orifice is narrowed there is a chronic condition of distension of the right ventricle, and

this is liable to dangerous increase under various circumstances, while digitalis is not to be implicitly trusted. The question whether bleeding should be employed or not then arises not unfrequently in mitral stenosis, and indeed the evidences of dilatation of the right ventricle, the occurrence of tricuspid regurgitation and distinct reflux of venous blood into the large vessels, are more common in this than in any other form of heart disease. But while venesection is at times as strikingly useful in mitral stenosis as in the cases of pneumonia alluded to, I have not often employed it. I may have lost opportunities through timidity or excess of caution, but I think it probable that the hypertrophy of the right ventricle, which is established during the gradual increase of pressure in the pulmonary vessels, makes the over-distension less dangerous. In deciding whether to bleed from the arm or not when there is mitral stenosis, account must be taken not only of the existing degree of distension and embarrassment of the right ventricle, but of the way in which it has been brought about. If it is the result of exposure to cold, or imprudent exertion, or emotional excitement in a patient previously manifesting little evidence of heart disease, then bleeding may be of the greatest service. In a lady to whom I was called when apparently in *extremis*, and who had been picked up on the stairs unconscious after emotion and exertion together, the action of the heart was so irregular, and the sounds so confused, that a diagnosis could only be arrived at by a process of exclusion. After eight ounces of blood had been taken she was greatly relieved. Next day the heart was acting more regularly, and a systolic tricuspid murmur was heard; a few days later the tricuspid regurgitation had ceased, and a presystolic mitral murmur was developed. With this change in the physical signs, which I have frequently noted, there was steady improvement, and the patient recovered, though she never regained her previous condition.

When, on the other hand, the distended state of the right heart under consideration comes on in mitral stenosis under the influence of the work and exposure of the daily life of the classes who come under our care in hospitals, the rest, warmth, food and care which they receive constitute such a difference in their favor that bleeding from the arm is rarely necessary; but I have often found six or eight leeches applied over the liver, enlarged and painful through venous congestion, of very great use. When, however, the venous stasis and failure of the right ventricle are the results of the valvular obstruction gradually developed in spite of favorable conditions of all kinds, bleeding, whether local or general, can be of little service. The last occasion on which I have employed general bleeding for the relief of over-distension of the right ventricle was in October, 1882. A man, aged about fifty, was admitted into St. Mary's Hospital with a vague history of some acute pulmonary attack. He was suffering from obvious painful respiratory distress, looked pale and haggard, and complained of severe pain in the loins. His temperature was high, the pulse frequent and large but short, and the skin perspiring. There were physical signs of bronchitis, but not sufficient to account for his dyspnoea. The heart was beating violently, the right auricle was distended, as was shown by dullness to the right of the lower sternum, and a systolic murmur was heard at the apex, but there was no evidence of mitral stenosis. His distress was so great and so clearly attributable to over-distension of the right side of the heart that it was determined to relieve this condition, although the cause which had given rise to it could not be satisfactorily made out. He was accordingly bled to

eight ounces by Mr. Spicer, my resident medical officer. This gave some relief, but it was not satisfactory, and was only temporary. After death, which took place two days later, it was found that a large thrombus had formed in the pulmonary veins, and having become detached had got entangled in the mitral valve; fragments had also been carried away in the circulation, and had lodged in various organs. This sufficiently explained the cardiac embarrassment and the failure of venesection to relieve it.

In another and very important class of cases the indication for bleeding is high arterial tension. It is not, of course, desirable to open a vein whenever the blood-pressure within the arteries is greater than normal, but only when this has reached a point at which it is attended with urgent danger. If no serious or threatening symptoms are present and time is allowed, the tension can be reduced by other means. The effects of unduly high arterial tension are characteristic, and the condition is as easily recognizable as an indication for venesection as is over-distension of the right side of the heart; the explanation, however, of the symptoms by the assumed cause and of the observed results of the treatment is not very easy.

The most striking illustration of the good effects of bleeding is met with in uræmic convulsions. No one who has tried venesection in these cases can, I think, fail to recognize its immediate efficacy and its favorable after-consequences. My own experience, at any rate, has convinced me of the value of such a mode of treatment. I may, by way of illustration, mention two cases which came under my care in St. Mary's Hospital within a week of each other, early in 1879. One was that of a boy of twelve, which was exceedingly interesting for several reasons. He was admitted for violent uræmic convulsions coming on in the course of scarlatinal albuminuria. One interesting point was that the convulsions were unilateral, illustrating the fact that one-sided convulsions may result from a condition affecting both sides of the brain. He was bled from the arm to eight ounces. The convulsions became less severe and soon ceased, but were succeeded by extraordinary maniacal excitement, not mere delirium; illustrating another fact with which I had previously become acquainted—viz., that a morbid condition which gives rise to convulsion may in a less degree give rise to maniacal excitement. This passed off in about twenty-four hours, and finally the albuminuria disappeared in less than a week. The other case was that of a little girl, also admitted for scarlatinal albuminuria and uræmic convulsions, who was bled, and, as in the boy, not only were the convulsions arrested, but within a week the albumen disappeared from the urine. She was readmitted on account of a relapse soon after her discharge, but again recovered.

It does not, however, necessarily follow that the *modus operandi* in the arrest of uræmic convulsions is by relief of arterial tension. This is, however, probable, as will be seen from the following considerations. The conditions present in uræmia, in addition to the high pressure within the arteries, which may possibly excite convulsions, are the contamination of the blood by urea or other urinary matters, a watery state of the blood, cerebral anæmia, and serous effusion. Now, abstraction of blood containing only its own proportion of urinous impurities cannot render that left behind more pure; it will indeed probably for the time be more impure, and will certainly be more watery from the absorption of fluid from the tissues to replace the blood lost. It can scarcely, therefore, be by any improvement in the quality of the blood, whether by removal of poisonous matters or by

correcting its dilution, that bleeding arrests the convulsions. The remaining conditions named, anæmia of the brain and serous effusion in the meninges, are possible effects of arterial tension, and their influence cannot be separately estimated. The same may be said of the minute capillary hæmorrhages supposed by Dr. Mahomed to be the immediate cause of the convulsions; if they are the proximate determining lesion, they are themselves the effect of extreme high pressure in the arteries. As regards the arterial tension, it is well known that it is raised in almost all diseases of the kidney; and it has always, according to my observation, become extremely high when uræmic convulsions are impending. Convulsions, moreover, are sometimes associated with inordinate arterial tension when there is no disease of the kidneys. Finally, in whatever way venesection acts as a remedy, it certainly lowers the pressure in the arteries. (I must here add, in order to avoid misunderstanding, that convulsions may occur when the arterial system is in the very opposite condition to that of tension, and that in epileptics the pulse is often—usually I should say—remarkably soft, short, and weak.)

But granting that extreme arterial tension is an invariable antecedent of uræmic convulsion, and therefore fulfilling the condition of a cause, this does not explain how the convulsions are produced. It is not yet definitely settled whether the obstruction to the passage of the contaminated blood has its primary seat in the capillaries or in the arterioles. If in the capillaries, then, notwithstanding the contraction of the arteries, which would on this hypothesis be protective, these minute vessels must be exposed to the distending influence of the high pressure in the arterial system, and capillary hæmorrhages or serous effusion will be a probable consequence. It has again been supposed that the forcible injection of the brain might so far expand it as to give rise to pressure on the venous sinuses and outlets, which would dam back the blood and cause a degree of stasis in the cerebral circulation. If, on the other hand, the stopcock theory of Dr. Johnson is true, and the primary obstruction is due to the contraction of the arteries, the supply of blood will be limited, and the pressure in the capillaries may be below that of the normal condition. The former hypothesis is, in my opinion, the more consistent with all the facts.

But it is time to describe the indication for venesection under consideration, and one more different from the flushed face and full bounding pulse, traditionally supposed to constitute this, could scarcely be imagined. The face is pale; when the fingers are placed lightly on the radial artery pulsation is hardly felt, and the vessel is usually small, though it may be large. The first impression is that the pulse is weak. When pressure, however, is made, so as to test the force of the current of blood, the pulsation is not easily extinguished, and the firmer the pressure the stronger the beat seems to be. At the same time the artery is full between the beats, and can be rolled under the finger like another tendon, or like a piece of whipcord. The heart will be usually found to be hypertrophied, and more or less dilated, and very commonly there is reduplication of the first sound over the inter-ventricular septum near the apex, due, as Dr. Sibson demonstrated, to want of synchronism in the systole of the two ventricles. When with these evidences of high arterial tension convulsions supervene, the most prompt and certain remedy is venesection.

Two cases have already been briefly related in which bleeding was of marked service in uræmic convulsions. The disease in both was acute scar-

latinal nephritis, and an illustration of its utility in chronic renal disease may be added. The patient was a lady, to whom I was called by Mr. Cripps Lawrence. She was, though comparatively young, the subject of contracted granular disease of the kidney, established apparently in previous pregnancies, and was again pregnant. She was suffering from vomiting, pain in the head, and confusion of the mental faculties, which had rapidly increased, and at the time of my visit she was in a state of stupor. The pulse was extremely small, long, and hard. It was evident that convulsions were impending, and Mr. Lawrence had already warned the husband of this. The warning was repeated; a nurse was set to watch the patient, and it was agreed to endeavor to avert the attack by purgatives and bromide, but that should convulsions come on venesection was to be performed at once, and then premature labour was to be induced. Within a few days the apprehended attack came on. The patient was bled, the convulsions were arrested, and a miscarriage was then brought about. The patient made a good recovery, and regained, and retained for some years, apparent health, under the judicious management of Mr. Lawrence. After various complications she ultimately died from cerebral hæmorrhage, and a post-mortem examination confirmed the diagnosis.

Whenever in kidney disease the symptoms of uræmic poisoning show themselves, vomiting, headache, confusion, stupor, muscular twitchings, etc., which experience has taught us lead up to convulsions, we almost always find the signs of undue arterial tension described, and we may confidently anticipate that venesection will at the same time diminish the pressure and relieve the symptoms. I have in several cases both of contracted granular and large white kidney, when cure was hopeless, diminished the suffering of the last few weeks of life, and changed the mode of death, by small bleedings, when the headache became intolerable and convulsions were impending. An example may be related in which bleeding was several times practiced.

The patient, a young man, aged twenty, was first admitted into St. Mary's Hospital in August, 1879, for a slight attack of diphtheria, which, however, set in with a convulsion. As he recovered it was found that he was the subject of chronic albuminuria, which explained the unusual mode of onset of the diphtheria. He recovered from the diphtheria and left the hospital, but returned on Nov. 16th, exhibiting all the marks of advanced renal disease and complaining of loss of sight. On ophthalmoscopic examination severe albuminuric retinitis was seen to be present, to which the impairment of vision, already serious, was due. The pulse exhibited all the characters of extreme arterial tension: it was long, hard, and incompressible, the artery being full between the beats, and feeling like a thick cord as it rolled under the finger. The boy was extremely pale and rather weak, but he was on the verge of uræmic complications; and on this account, and in the hope of saving the eyes from further damage, venesection was ordered to eight ounces on Nov. 19th. The form of disease affecting the kidneys was considered to be large white kidney from acute desquamative nephritis in process of contraction, and we were not altogether without hope that as bleeding is sometimes promptly curative in the early stage, it might be of service even then. The patient was relieved, and the eyes certainly did not seem to get worse as fast as before, if, indeed, they did not improve; the pulse became larger, softer, and shorter. There was no perceptible difference, however, in the state of the urine, and the symptoms gradually returned, in spite of the usual treatment. On De-

cember 17th he was apparently moribund, excessively pale, scarcely conscious, with headache, muscular twitchings, and all the signs of impending convulsions. The pulse was small and long, though not very strong as the heart was acting feebly, the artery was full between the beats and could be rolled under the finger. It seemed as if the loss of an ounce of blood would prove fatal, but as he was clearly about to die and no other treatment offered him a chance, he was bled to eight ounces. The effect was remarkable. He began at once to improve, and so far rallied as to get up daily and to go about the ward and to enjoy his food. The tension, however, which was markedly lowered, gradually increased, but we hesitated to take away more blood from a patient who was so extremely anæmic. As we declined the task copious epistaxis came to the patient's relief. On Feb. 11th, after premonitory symptoms for some days, convulsions again came on, for the relief of which my resident, Mr. Havell, at once bled to twelve ounces, and as uræmic symptoms were still very severe, and the arterial tension very high, on Feb. 14th he was further bled to eight ounces. After this the confusion and stupor disappeared, and the patient became quite clear in his mind; but he died on Feb. 16th, remaining rational to the last. On post-mortem examination the diagnosis of large white kidney becoming granular was confirmed.

But high intra-arterial pressure may exist independently of kidney disease, and may give rise to convulsions when it reaches a certain degree of intensity. In 1877 I reported to the Clinical Society a case illustrating this, in which venesection was attended with remarkable success. It may be reproduced here, and is as follows:—

The patient came to my consulting-room on Wednesday, July 25th, 1877, saying that on the previous Monday morning he had an apoplectic attack. All that he knew about it was that, on coming to himself, at about 6 A.M., he found the house had been roused and a medical friend, Dr. Gaven sent for. He pointed out a general discoloration on the forehead and chest, which was found to be due to innumerable minute capillary extravasations, and I inferred, what turned out to be the case on inquiry from his wife later, that there had been convulsions. He said he had had a little headache after the attack, but that he then felt perfectly well, and he laughed at the serious view taken of the case. While he was talking with me I observed several momentary suspensions of consciousness, during which he lost the thread of his conversation or ceased to hear what I was saying. I had seen this gentleman before, and knew the main facts of his medical history. He was about forty-two years of age, inclined to be stout, and slightly florid. He was of an excitable disposition, and intellectual in his pursuits. He had spent much time abroad; had lived freely and heedlessly, but had not been given to excesses; had had syphilis when young; had taken much mercury and iodide of potassium, and the last manifestation, which had been rupial ulceration, of which he bore many scars, had taken place eighteen years ago. Exactly twelve months before he had had a carriage accident, in which he received a very severe concussion of the brain, and was supposed to have sustained fracture of the base of the skull. He had been unfit for professional work for three months, and on his return to it did very little for some time, and was extremely careful in the matter of diet and drink. Little by little he had increased his work and thrown off the restraints imposed upon him, and resumed his old convivial habits. He acknowledged that he was more irritable than before the fall, but considered

that no other ill effect remained, except that he had lost the senses of smell and taste. After hearing the patient's account of the attack and making the observations mentioned I sent him home, ordering him aperient pills and small doses of bichloride of mercury.

Next morning I was called to him, and reached his bedside between 7 and 7.30 A.M. I found there Dr. Gaven, and learnt that our patient had had a succession of violent convulsions from about 3 A.M., at intervals of about fifteen minutes, and had been unconscious the whole of that time. He was lying on his back unconscious, tossing restlessly, throwing about his arms, and groaning loudly. The face was expressive of suffering, the eyes closed and held firmly shut when the attempt was made to open them, the pupils equal and of moderate size. It was noticed that the left arm was moved less than the right, but on careful watching it was apparent that the reason for this was some injury to the muscles about the shoulder-joint, and there was no evidence of hemiplegia or paralysis of any kind. The heart was beating violently, but the sounds were normal. The pulse was rather small and weak, but long, and the artery was full between the beats. When an attack of convulsions was coming on the groaning ceased, and the limbs were at rest. The eyes were then opened widely, their look and the expression of the face being for a moment almost natural, but the pupils quickly dilated, the cornea was turned up under the eyelid, the face became distorted, and there came a long and fearful groan, or almost scream, at the end of which the entire body and all the limbs, were convulsed with violent synchronous jerks. The face became livid, the pulse imperceptible, and the heart-beat weak, and it seemed as if life were extinct. This would, I think, really have been the case had it not been for Dr. Gaven, who at the critical moment of each attack got a spoon between the teeth, depressed the tongue, and started respiration artificially by pressure on the chest till the respiratory movements began to be re-established.

While we were discussing and deciding upon the line of treatment two attacks occurred, notwithstanding administration of chloroform. Mustard poultices had already been applied to the calves and to the nucha. A dose of calomel was placed on the tongue. An enema was ordered, and then bromide of ammonium, or potassium, with chloral, was to be injected into the rectum. Any effects to be hoped for from these measures, however, would require time, and every hour was full of peril. We consequently decided to bleed the patient. This was done by Dr. Gaven to at least thirty ounces. The pulse did not falter during the flow of blood, but became larger and softer. There was no other apparent effect at the moment. Another convulsion came on, the third I witnessed, almost before the bandage could be adjusted. It was as violent as any of the others, but it was the last. The convulsions from this time ceased entirely. In the afternoon the patient had regained consciousness, but could not speak. Next day he talked very well, but his ideas were rather scattered. In another day or two his intellect was quite clear, and except that he felt very stiff everywhere, and had pain in the left shoulder, to the muscles of which some injury had evidently been done by the convulsion, he declared himself to be quite well. Bromide of potassium was given, and Dr. Gaven carefully watched the progress of the case. For some time there was much jerking of the limbs during sleep, and once or twice some apprehension was excited by pain in the head, or excitement of manner, but there was gradual improvement, and very soon the patient was able to

do a little work. He recovered completely, and is now (Dec. 1882) perfectly well.

Another example of successful bleeding is worth relating, and the more so as the case did not come under my observation till afterwards. The patient was a young lady, aged about twenty, who was brought to London for my opinion in October, 1879, with a letter from Dr. A. Newington, of Wheatley, from which the following is abstracted:—She had enjoyed good health, but suffered from constipation and piles, took plenty of exercise, was abstemious in diet, and took no stimulants. The catamenia had been absent for some months, and while abroad during the summer she had suffered from fulness in the head and disinclination for society, and when she walked up hill her face became purple, and she felt as if about to have a fit. These sensations had increased to an extreme degree; the conjunctivæ were injected, and the pulse full and throbbing; the symptoms were so urgent that Dr. Newington at once bled her on Sept. 21st to thirty ounces. She lay down for an hour, had lunch, and felt so much better that she went to church. Slight discomfort in the head was all that remained, and for this bromide was given, aloe and myrrh at night and Friedrichshaller water in the morning being also ordered. In two or three days she seemed to be quite well; and she so remained till Oct. 14th, when Dr. Newington was again called to the patient on account of a similar but milder attack. Menstruation, however, now came to her relief. I saw this young lady at the end of October; and although she then considered herself perfectly well, there was still high tension in the pulse, and there could be no doubt that it had risen to the point of danger, when she had the fulness in the head and other symptoms. In my opinion, indeed, the bleeding averted a serious catastrophe.

The injurious effects of high pressure in the arterial system are not confined to the production of convulsions. These, indeed, are rare and exceptional, while innumerable lives are shortened by it in other ways. Even moderate excess of tension in the long run produces disease of the vessels, or of the heart, or of both; and it was in such a condition of the circulation which was accurately recognized by the more discriminating of our forefathers that the "spring and fall bleeding," which was so common, would really be of service. I venture, indeed, to affirm that many lives might be prolonged, and many attacks of paralysis averted, by a revival of this practice in certain cases, not that no other means are available, but because such patients would submit to an occasional periodical loss of blood, while they will not exercise the habitual self-restraint and abstinence required to carry out a plan of treatment which must extend over months and years.

I am particularly anxious that it should not be supposed that bleeding is indiscriminately recommended as a remedy for convulsions. Only when high arterial tension is present should it be employed. For this reason I relate the following case:

In November, 1881, a strong and previously healthy laboring man was brought into St. Mary's Hospital, who had for some hours passed from one convulsion into another with short intervals of complete unconsciousness. The convulsions were violent, but presented no special feature. There was no history of previous attacks of the kind, or of kidney affection, or of other disease. The temperature had gone up to 104°, and my resident, who had seen the good effects of venesection in uræmic convulsions, had already bled the patient to sixteen ounces before I saw him. The pulse, however, instead of being small, long, and hard, was very large, full, soft, and short; it was the

typical full and bounding pulse; the arteries dilated to the utmost, the blood rushing through them in full stream. There were features about the case which led me to anticipate a fatal result; the loss of blood had produced no effect, and as the amount taken, though considerable, was inadequate if any decided impression was to be made on such a case, he was again bled. There was still no apparent result. The temperature continued high, the unconsciousness persisted, the convulsions recurred, and the patient died. Nothing abnormal was found in the brain to account for the convulsions, nor was any morbid condition of importance discovered in any organ.

It was formerly the practice to bleed after severe injuries to the head, especially when symptoms of so-called cerebral irritation came on. I have no doubt there are cases in which it would be of very great service, but it is a matter in which I have no experience. It might seem at first sight that bleeding ought to be a valuable resource in cerebral hæmorrhage; but careful thought would lead to the conclusion that its operation could only be extremely limited, and this is what is found in practice. We should not be so liable now to take the effects of embolism and thrombosis for those of rupture of a vessel, and so do serious harm instead of good; but in a large proportion of cases of cerebral hæmorrhage the mischief is done before the patient comes under observation. In ingravescant apoplexy, however, the oozing of blood appears to continue for some time, and as this form of attack is almost invariably fatal, it would be well worth while to try what bleeding could do. I have seen only one case sufficiently early for such a trial, and in that a vein was opened first in one arm and then in the other, but no blood could be got to flow. Mr. Boon, now of St. Kitts, who was then resident medical officer, actually passed a probe upwards and downwards in one of the veins. We were about to open the jugular, but here we had difficulty in getting the vein to fill, and while we were engaged in the attempt the vomiting, which is one of the symptoms of ingravescant apoplexy, came on and compelled us to desist. The chance of doing good was now over, and the patient gradually became comatose and died. The enormous clot usual in these cases was found just outside the corpus striatum.

While bleeding comes too late when an artery has already burst in the brain, it might often avert such an event, and when the indications of excessive arterial tension have been well mastered, and are distinctly recognized in a patient who presents any of the premonitory symptoms of apoplexy, venesection ought to be fearlessly practiced. Almost every medical man will have seen cases in which epistaxis has at once brought relief from threatened apoplexy, and it is in our power to afford relief equally efficacious.

It is probable that there are other conditions in which bleeding would be of great service; but it is better to proceed with extreme caution in the reintroduction of this practice. There is a strong prejudice against it in the public mind, though not, in my experience, so strong that it will be forbidden when it is recommended by a medical man who has confidence in its power to do good; and this makes it important, in the interest of the medical man, that there should be no doubt as to its beneficial effects whenever it is tried. The great service, again, which venesection is capable of rendering in suitable cases is a weighty reason for desiring that its employment should not be retarded by resort to it in cases where its effects are doubtful. The ground gained should be made sure by experience before further advance is attempted.

Seymour-street, W.

NOTES ON A CASE OF HÆMATO-CHYLURIA.

By JOHN D. HILLIS, F.R.C.S., F.R.M.S.

On March 26th, 1882, a sample of urine was forwarded to me for examination, together with the following history.

W. E. B—, aged forty-two years, a colored Creole of Demerara, stout and florid, has been for the past two years suffering from intermittent hæmato-chyluria, previously to which he had always been a healthy man. The patient is not losing flesh, but complains of an aching pain in his loins. Normal quantity of urine is secreted daily; skin acting well; pulse and temperature normal. On cooling, the urine is said to become like blanc-mange. The specimen of urine was of the color of port-wine; reaction neutral; specific gravity 1025, and contained a quantity of albumen. Examined microscopically, the field was covered with well-defined red blood-corpuscles, the urine also contained vesical mucus and some crystals of triple phosphate. It was late in the evening and only a cursory examination could be made. On March 30th I examined another specimen which contained a quantity of fatty granules, crystals of triple phosphate, a few chyle, but no blood-corpuscles; and there were a few cells of bladder epithelium, but no flariæ could be discovered after a very careful examination. On April 5th another specimen of W. E. B—'s urine was examined with $\frac{3}{4}$ and $\frac{1}{2}$ objectives. There were fewer red corpuscles, but an adult flaria sanguinis hominis was discovered on the second slide examined. I advised the patient being placed on decoction of rhizophora racemosa, which I have found most useful in cases of chylous urine. Under this treatment the patient considerably improved, the blood has entirely disappeared, and the urine does not coagulate on cooling. He states that "occasionally his back aches, and then his water becomes a little cloudy." I have had no further opportunity of examining either blood or urine, as he lives in a neighboring county; but I can strongly recommend the mangrove bark in these cases.

British Guiana.

A CASE OF RECOVERY AFTER A BROKEN NECK.

By C. JORDISON, M.R.C.S.

On Oct. 26th, 1881, Mr. C. S. P—, aged thirty-eight, when out cub-hunting, was riding at a canter over a fence under the arm of an oak tree, when his horse jumped much higher than he expected, and the back of his neck came in violent contact with the concave surface of the branch. Mr. P— was leaning very forward over his horse's neck, and as the horse jumped almost perpendicularly upwards, the force of the blow was forwards and downwards. He was knocked off his horse, and lost consciousness for about two minutes. As soon as he could speak, he complained of intense pain up and down the neck and in his arms and legs. In less than ten minutes I was with him, when his first words were. "I am done for; my arms are paralyzed, and the paralysis is extending over my body and into my legs." I noticed the respiration was normal. We carried him on a gate to the nearest farmhouse, where, after examination, I came to the conclusion that there were fractures of the laminae of the fifth and sixth cervical vertebrae. At this time there was complete paralysis both of motion and sensation of the left upper extremity, and almost so, though to a less extent, of the right; impaired mobility of the left

leg, the right being unaffected, and a sense of tingling and numbness over the whole body; there was perfect consciousness, and great pain in the neck and shoulders. He was laid upon a hard and perfectly flat mattress, with the head on a level with the shoulders, and this was kept immovable by sandbags. On the following day Mr. Bickersteth, of Liverpool, saw the patient with me. He concurred with my diagnosis, and we agreed that the paralysis was from injury to the roots of the fifth and sixth spinal nerves, and that the numbness of the body and partial paralysis of the left leg were due to extravasated blood outside the sheath of the cord. There was of course paralysis of the bladder, and for a few days slight difficulty in swallowing. The temperature never rose above 101.4°. There was for a few days slight delirium and occasionally very great flushes, the whole head, neck, and face becoming of a deep-red color, and this was always succeeded by great restlessness and irritability. By the third day he had entirely recovered motion in the left leg, and there was only slight tingling as far as the knee.

The treatment was absolute rest, but on the ninth day it was essentially necessary to change the bed linen, etc.; and whilst this was being done crepitus was distinctly felt by the trained nurse, and heard by my assistant and myself. After this time the head was not moved again for many weeks. By the fourteenth day he had much greater power in the right arm, and he could just raise the left, but could hold nothing between the fingers; there were still numbness and tingling over nearly the whole body, also paralysis of bladder and spincter ani. Perfect power of motion in both legs. Temperature 98.2°, pulse 99, respiration natural. There was a large amount of extravasated blood under the skin as far as could be seen down the neck, and extending from the spine to the left shoulder-point. After this time the paralysis of the arms became gradually worse, until at the end of the fourth week there was then complete loss of power of motion over the left arm and hand, accompanied with intense hyperæsthesia; almost complete paralysis of the right arm and hand, but less hyperæsthesia. On the left side there was complete atrophy of the hand, arm, and shoulder, the two pectorals being the first to waste away; on the right side there was also some atrophy, but to a less extent.

This condition of utter helplessness continued without material change for about a week, when the power of emptying the bladder and of making an effort at defecation began very gradually to return, and slowly the power of moving the right arm was recovered so that by the eighth week he could hold an envelope or toothpick, but could not support a light book or even a newspaper. By the end of the eleventh week he could do as much with the left arm, the hyperæsthesia was gradually subsiding, but all the joints of the left arm and hand were very stiff and gave us much trouble. At this time he could slightly raise the head from the mattress and could rotate it freely. At the end of the thirteenth week I had my patient carried a distance of four miles on a stretcher to his own house, after which he began to make rapid strides towards recovery, and as the callus from around the fractured ends of the bones was absorbed, and the muscles again received their nerve supply, so he gradually recovered normal sensation in both arms and over the trunk and less rapidly the power of motion. At the end of the sixteenth week he was up and walking about; there was decided prominence over the seat of the injury, and the head was unnaturally tilted forward, but only to a slight extent, so slight that it would not be noticed by anyone who had not known Mr. P—

before the accident. The sensation and motion in the right arm were perfect, the sensation in the left nearly so, but there still existed great weakness, although there was no perceptible or measurable difference in the size of the two arms, the muscles having become developed more rapidly than they atrophied. At the end of the twenty-fifth week my patient was riding, driving, rowing, and swimming, having gone to Margate (by the advice of Mr. T. Bryant, who saw him about this time), and with the exception of a slight weakness in the left arm was perfectly well and strong.

Remarks.—I think undoubtedly we had here an injury to the spinal nerves by the broken fragments of the injured vertebrae, as the paralysis, numbness, etc., were instantaneous. The paralysis of the left leg came on after a few minutes, and was probably due to blood extravasated outside the sheath of the cord. I think the extreme paralysis about the fourth and fifth weeks was due to callus thrown out around the end of the broken fragments pressing upon the nerves as they emerge through their canals, and as this callus became absorbed so the power of motion, the sensation and the growth of the muscles were gradually recovered, and the now continuing weakness I attribute to there having been some slight laceration of the sheath of the nerve as it emerges from its canal, and the resulting thickening pressing upon and destroying some of the nerve fibres. I attribute the unusual and happy result primarily to there having been no interference with the respiratory tract, the injury having occurred just below the point of origin of the phrenic nerve, which possibly, in this case, did not receive a communicating branch from the fifth cervical; and, secondarily, to the great muscular development of my patient enabling him to withstand the ill effects of long-continued pressure without the usual consequences, and to the fact that although the spine was broken the spinal cord was not injured.

Malpas.

NOTES ON A CASE OF PRURIGO FEROX; TREATMENT AND RECOVERY.

By Surgeon SHIRLEY DEAKIN, F.R.C.S., Eng.,

Officiating Junior Civil Surgeon, Allahabad.

As cases of Hebra's prurigo, fortunately for the unhappy patients, are rare in England, the following notes of a case successfully treated may be of interest. Dr. Tilbury Fox states in the last edition of his valuable work on "Skin Diseases," p. 156, that he had only met with one case. The case under observation presented little in common with cases of Scabies ferox, or Malabar itch, which are fully described in Drs. Fox and Farquhar's "Skin and other Diseases of India and Hot Climates," pp. 65 and 267.

Constable N—, aged fifty-two, a Punjab Mussulman, was admitted to the Police Hospital on Oct. 26th, 1878, suffering from severe itching of the skin of the whole surface of the body, excepting the palms of the hands and the soles of the feet; the back of the hands and the front of the feet, however, being especially troublesome.

Previous history.—Has suffered much from periodic (so-called "malarial") fever in past years. States that twenty-two years ago, at Peshawar, the eating of *bhara*, a kind of sheep, used to give him fever constantly. He denies a syphilitic history.

Present history.—Six months since he first noticed a severe itching between the shoulders, and presented himself at the hospital a month later on. Then he had much heat in the skin, and perspired freely during the night. When I saw him first the

skin was but slightly thickened. Both lenses exhibited an advanced cataractous appearance, a condition very common at his age among natives of India. Bowels regular; tongue clean and firm; passes his urine slowly, but his febrile condition prohibited any attempt at exploring the urethra. He has a reducible right inguinal hernia, and there is a small swelling over the site of the left internal ring.

Present state.—The whole of the skin, excepting that over the scalp, chin, armpits, groins, and hernial sac, is much infiltrated and thickened. When uncovered the patient shivers greatly. He is terribly tormented with a constant itching, and scratches at his skin in a most distressing manner. His beard has fallen out, and the hair on his chest, which was abundant, has also disappeared, likewise the hair from the scalp; the moustache is firm. There were numerous slight abrasions all over the skin, caused by his nails; these rendered it difficult to decide whether the patient suffered from phthiriasis or not; repeated examination, however, did not reveal any parasite.

Treatment was first commenced with three hot air baths with sulphur, quinine and iron being given internally; and weak carbolio oil, one in forty, freely applied over the skin. Subsequently he took five minims of solution of arsenic three times a day, and applied sulphur ointment, and then linseed oil only. Potassium iodide in fifteen-grain doses twice a day, first alone, and afterwards with the addition of one-sixteenth of a grain of chloride of mercury, produced no effect; and on December 15th, after six weeks' treatment, he was sent to his home in the Punjab on two months' sick leave no better. He was readmitted to hospital on February 20th, 1879, on return from sick leave, no better for the change. His state is thus noted: skin much thickened, as before described, and though he is fairly nourished, he is much troubled by the itching. Ordered fifteen grains of powdered ergot twice a day. To have an alkaline bath: three ounces of bicarbonate of potash, two ounces of bicarbonate of soda, one ounce of borax, and one pound of bran, in thirty gallons of water. To use as a lotion: one drachm of hydrocyanic acid, two drachms of borax, one fluid ounce of solution of acetate of ammonia, in eight ounces of water. During his stay in hospital he had four baths as above, and took ergot for more than one month. He applied the lotion, using a bottle in eight days. Subsequently he took five minims of solution of arsenic three times a day. Small lumps appeared on the skin somewhat resembling mosquito bites, only often they were much larger, measuring an inch across. They were hard, raised and redder in color than the surrounding skin. Each remained for half an hour or so, and then died away. When at his worst, some fifty or sixty such tubercles appeared daily.

Under treatment his condition greatly improved, the thickening of the skin disappeared to a large extent, the inner surfaces of the thighs remaining the worst. On the 24th of June he was convalescent and discharged to duty, doing his duty well until, on the 5th of October, 1879, he came up for examination previous to his discharge on pension. His state was then as follows:—Infiltration has disappeared from the skin of the face, and the face, consequently, looks much smaller; he has lost the peculiar smile, which recalled the risus sardonius to one's mind, and which was due to excessive thickening in the region of the zygomatic and risorius muscles, and about the eyebrows. His beard has grown again thick and long; it is four inches in length, and the hair is quite black, as is also the hair on his chest, which has grown again luxuriantly. Before his illness the hair was nearly

white. The hair on his head and in his moustache is now abundant, and of a dark-grey color. He has not taken any medicine since he left hospital. Shortly after his discharge from hospital he came to the native doctor, Hospital Assistant Ram Lal Das, and asked him whether he had been given arsenic in hospital. His reason for doing so was that his friends had attributed the change in the color of his hair to the administration of arsenic. It appears that the effect of arsenic in causing hair to become black is well known to natives. I have consulted Neale's Digest, Ringer, Fox, and Bartholow, but cannot find any reference to this therapeutical effect of arsenic. There is still some slight itchininess of skin on the inner sides of the thighs, and slight thickening on the inner sides of the forearms. He is now free from the troublesome perspiration. The gums are slightly spongy; a scorbutic tendency, however, is generally prevalent among the poorer natives, owing to the scarcity of vegetables and high price of food stuffs now current in this district. The man is well satisfied with his changed condition. When first treated, Dover's powder, belladonna, and ether were given to check the perspiration, but without effect. Ether, for suggesting the use of which in checking perspiration I am indebted to Dr. Balthazar Foster, has generally been in my hands most successful in doses of from ten to twenty minims of spirits of ether. It, however, is very volatile, and any mixture containing it should be dispensed daily and kept in a glass-stoppered bottle.

Allahabad.

THE MICROSCOPE IN DIARRHOEA.

By KENNETH W. MILLIGAN, B.A. Cantab.

THE use of the microscope as a common aid to diagnosis and treatment must inevitably take a prominent place in the future; and the demonstration of the bacillus tuberculosis by Koch, and the subsequent and progressive simplification of the process by Ehrlich, Baumgarten, and Heneage Gibbes, show how indispensable this instrument will become in the not far distant future to the practitioner of medicine. A series of cases of diarrhoea have recently occurred in this district in which certain features of interest were observed. The patients were all attacked when a few days of very hot weather had been followed by considerable rain. A sort of period of incubation occurred, during which the patients were depressed and out of sorts, and this was followed by a prostrating attack of diarrhoea. The stools were fluid, not unlike those of typhoid fever, and contained in every instance, small gelatinous or albuminous lumps like half-cooked white of egg. The odor was extremely offensive. Beyond the prostration, however, and general gastric disturbance, with excessive flatulent distension and pain, there were no constitutional symptoms. In no case was there any marked rise of temperature, nor was the pulse greatly affected.

Having several cases at the same time under unsuccessful treatment by astringents, powdered aromatic chalk with opium, etc., I submitted the evacuations to microscopical examination. This showed them to be swarming with bacteria, and the indication for treatment drawn from the examination was carried out by the exhibition of one grain and a half of carbolic acid in compound tincture of cardamoms and peppermint water every four hours. The later cases were treated by the exhibition of five minims of terebene in mucilage every three hours. This treatment proved in the

highest degree satisfactory, for the unpleasant symptoms were speedily and effectually checked.

The method of examination for bacteria which I have found successful is very simple. The stain used is a solution in distilled water of "navy blue," one of Tomlinson's aniline dyes. I have generally used it of a deep-blue color, but not of any particular strength. A lump of the gelatinous matter before referred to is well smeared over the surface of the cover glass and allowed to dry. The cover glass is then floated on the dye for five or ten minutes, at the end of which time it will be found well stained. It is then washed in dilute nitric acid (1 to 3) and finally in distilled water. The cover slip is then allowed to dry, which may be aided by gentle warmth from a spirit lamp, and mounted in Canada balsam. Evaporation is a better method of extracting the water previous to mounting than immersion in alcohol, for I have found the alcohol to obscure the lustre of the aniline dyes. If preferred after the washing, the cover slip may be floated on a solution of aniline brown, made from another of Tomlinson's dyes in a similar manner. These dyes are excellent in microscopic staining, and are moreover cheap, and easily made as required. The most useful appear to be magenta, navy blue, and Bismarck brown. The violet has not proved so successful in my hands. The bacteria so observed consisted of small refractive granules (micrococci?); short, fine rods (bacilli); long, fine-pointed rods; and curled, twisted ones. There were also mycelium-rods, frequently stretching right across the slide. All these were well seen with $\frac{1}{2}$ in. object-glass, and even with $\frac{1}{4}$ in. It is of course to be noted that the evacuations should be obtained as fresh as possible for examination. I directed terebene to be at once placed in those that were put aside for me, and they were then well covered up.

Aitken speaks¹ of "the presence of a bacteria development in the stomach and intestines, under the name of *mycosis intestinalis*." The class of cases, however, to which he refers, appear to be of a much more serious character than my own, and are said to occur "suddenly during apparently robust health, quickly followed by lividity of hands and face, collapse and death in from two to six days."

Kington, Warwick.

COMPOSITION, RESOLUTION, AND ABEYANCE OF SECONDARY PERCEPTIONS.

By Brigade Surgeon T. OUGHTON,

Army Medical Department.

DIRECTIVE phenomena are affected by muscles influencing one another, as well as by the mechanical arrangement of their constituent fibres. Such was a cursory rejoinder to a hypothetical objection to the motor diathesis of the secondary perceptions on the ground of the multifarious and incongruous distribution of the fibres of certain muscles—the pectoralis major, pennisiform muscles, etc. It is a rejoinder meriting critical examination, since the problem of secondary perceptual currents being conducted centripetally from a voluntary muscle during its vital contraction must be incompletely verified, if not quashed, without its due acceptance. Taking it, then, as a text for the present remarks, I trust that abundant evidence will be forthcoming in its support, which will also have a practical bearing on the further proof of the problem in question.

Composition.—A very good and simple illustration

¹ Science and Practice of Medicine, seventh edition, vol. ii. p. 88a.

of this nervous process is afforded by the following observation:—"The left eye may perceive an object eight degrees to the right of the main line of direction, and the right eye four degrees; but binocular vision will give it its correct value of six degrees by virtue of muscular co-operation and the agency of a directive composition." It is an absolute essential for the dynamic composition of secondary sensorial forces that the muscular fibres engaged in the operation be consensual—that is, pull in the same direction more or less. 1. Note the parallelism of the elementary fibres of a voluntary muscle in contrast to their intricate interlacings in an involuntary and non-directive muscle. They would doubtless have been perfectly parallel were it not for the convenience in packing, admirably shown by Paley, arising from thin tendinous sheets and delicate cords. Composition renders perfect parallelism unnecessary, however; the fibres agree in their general direction, and the muscle's contraction generates a single directive resultant. 2. Observe how the numerous muscles of a set (flexors on the forearm) operate sensorially as one muscle would do when unified in one particular action (flexing the hand). Many muscles are indispensable for the attainment of various distinct ends, but muscular consent originates a directive unification where it would be useful. 3. The phenomenon of single vision has been interpreted by a consensual theory; the external rectus of one eye pulls in the same direction as the internal rectus of the other eye, thereby initiating a directive composition. There is a strict analogy between this case and that of a single muscle or set of muscles. Hence an objection to the motor diathesis of the secondary perceptions, on the ground of the extremely irregular form (pectoralis major), or distribution of the elementary fibres (penniform) of certain voluntary muscles is a weak one. Should it be sought what single directive message any muscle (penniform or otherwise) transmits to consciousness, it will be necessary merely to note the relative positions of its osseous attachments, and the direction towards which the movable segment is turned by its shortening, so that the directive message is determined by the mechanical conditions of a muscle's origin and insertion. But, mark here, nothing will be more natural than to conclude that this result could not obtain excepting the relative positions of osseous origin and insertion are known by a sort of inner consciousness; the superior rectus, for instance, rotates the ocular globe upwards, it may be concluded that the resulting upward idea has no *points d'appui* for its realization in the absence of a recognition of the sites of origin and insertion of the muscle by a latent process of consciousness. I regard such a conclusion as erroneous, inasmuch as latent or inscrutable consciousness is incomprehensible; the directive message, although due to mechanical conditions, has no further reference to them, referring only to any sentient point or points that may be impressed *ab externo*. Thus, the biceps has a sensorial reference to any impressed sensitive point either on the hand or the forearm, and not to its bony attachments; again, the muscles rotating the body or the head may have a directive inference to an impressed retinal point. From a very simple starting-point we now find ourselves at the complex borderland where the Ego and the Non-ego meet; there is the natural cohesion of the insensate tendinous and bony origins and insertions (the Non-ego) in juxtaposition with and holding relation to an independent agency—namely, the vitalized cohesion of muscular contraction (one mainspring of the Ego). Nothing remains for us apparently but to contemplate these two stupendous forces standing thus face to face; a fair simile

of the position is to be found in a pair of horses drawing a tram-car round a corner, the animals being guided as it were by the *vis a tergo* of the heavy tram with its mechanical adjustments.

Resolution.—It is an almost axiomatic observation, where one finds composition there one may search for resolution; and it would seem that the latter process is in operation to produce the visible directions of the peripheral portions of the retina. Before entertaining this subject, however, let us consider the direct proofs that visible direction is a motor physiology in the following condensed argument:—

1st. Peripheral retinal points are equally sensitive with the axial point, noticeable in the observation of minute stars; therefore, on the theory that the special nerve of sight is a directive agency, the centre of visible direction will correspond with the centre of the retinal concavity (ocular centre). Sir David Brewster has promulgated this view.

2nd. Prof. Volkmann and Dr. Griffin have shown, each by an independent investigation, that the centre of visible direction is situated at a point considerably anterior to the centre of the retinal concavity; therefore visible direction is not effected by the retina.

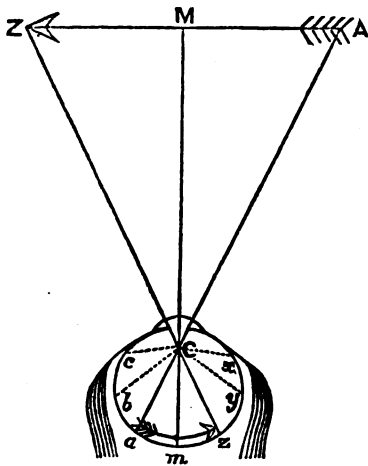

3rd. Every object before the single eye, whether median or lateral, is seen accurately in position; therefore the centre of visible direction coincides with the eye's optical centre. The latter is at a point in the crystalline lens near its posterior border—that is, anterior to the centre of the retinal concavity.

4th. Every object appears to be fixed during the rolling of the eyeball (Brewster); therefore the optical centre and the centre of visible direction both coincide with the centre of rotation of the eyeball. Hence (*nisi prius*) visible direction results from the motion of the eye—i.e., its muscular apparatus.

Reference being now made to the following figure, *c* being the optical centre, the straight line, *m m*, will represent the median and main line of monocular visible direction. This line is regarded as being originated by the recti pulling the eyeball evenly backwards by their normal tonicity. Muscular tonicity, according to this view, is a directive agent as well as volitional contraction, and the opinion is corroborated by the directive phenomena resulting from the erect position of the body and the head, both postures being referable to tonicity. The balance of the recti is destroyed when the eye is directed laterally. If the eyeball be turned towards the right, the rectus so rotating it is in a more active state of tension than its fellows, and consequently the axial point, *m*, will now perceive the image depicted on it along a line of direction inclining to the right. But the lateral points *a*, *b*, *z*, or *y* are each equally affected by the greater tension of a given rectus, as is point *m*. How is it that the images impressing these points are not perceived along a line of direction that is parallel to, or identical with, that of the image on the point *m*? Herein consists the paradoxical problem of visible direction. I hold that the main direction *m c*, is resolved into the oblique visible directions *a c*, *b c*, *z c*, *y c*, etc.

Such resolutions appear to be warranted when we consider the instability of peripheral retinal points as compared with the stability of the axial point, and that said stability is progressively greater in the direct ratio of the distance of any peripheral point from the axis. Assuming the eye to be looking forwards, it will be manifest that the backward pull of the entire recti operating on the axial point, *m*, would draw the eyeball backwards, whilst if operating on any oblique point, *a* or *z*, it would tend to rotate the eyeball. Again, the mo-

bility of this rotatory influence will be greater as exerted on point *b* than on point *a*, on point *c* than on point *b*, and so on. Further, the tendency of the muscular action to pull the eyeball backwards, will be inversely as the tendency towards its rotation; hence the forward direction, *m c*, originating with the backward pull, will be modified accordingly. A visible direction corresponding to any oblique point, *a* or *z*, will not originate such a forward idea as the point *m*—that is, it will be inclined to right or left in addition to forwards; neither will a visible direction corresponding to points *b* or *y* originate such a forward

idea as the less oblique points *a* or *z*—that is, it will be more inclined towards the right or left. Thus the causation of the progressive scattering of visible directions from retinal centre to circumference, as with other directions, is determined by a mechanical condition (the globular shape of the eyeball). The backward pull (the forward idea) will be very slight at the peripheral points *c* and *z*, but it is still there; in other words, the main direction *m c*, is resolved into the dotted lines indicated in the diagram.

In what manner the site of the centre of visible direction is fixed at a point *c*, correspondent with the eye's centre of motion, is a less abstruse inquiry. That the progressive scattering of visible directions must cause them to intersect at a common point eventually, will be evident on considering that the directions are different on either side of the median line *m c*, and that the eyeball is globular. Why, then, at point *c*, or how are the visual angles, *m c a*, *a c b*, etc., generated? Confining our attention to the images *m* and *a* of the objective entities, *m* and *a* with visual angle *m c a*:—(1) Retinal points are impressed by light for one-eighth of a second. (2) The glances of the eye must be considerably more rapid than this, since even the movements of the hand are more rapid; an ignited piece of charcoal revolved in the hand deceives the retina by producing the semblance of a fiery circle. (3) Therefore, in directing the eye rapidly from object *m* to object *a*, the retinal points *m* and *a* will be impressed by the images of these objects simultaneously for a definite period. (4) Therefore the visual angle *m c a* will be identified by perception, and this angle will be formed at point *c*, the eye's centre of motion. (5) Therefore every single visible direction into which the main visible direction is resolved will have a fixed value for a certain retinal point; thus, *a c* for the lateral point *a*. Let it be understood that muscular traction reacting on the

mechanical sphericity of the retina generates visible resolution, whilst ocular rotation effects monocular visible direction.

Other phenomena that are probably determined by directive resolution may be briefly alluded to: I refer to the visible area correspondent to the punctum caecum, and to the resolution of main tactile directions correspondent to the manifold sentient points on the skin's surface. The latter forms a fit subject for reflection and analytical investigation.

Abeysance.—There are two varieties of this process—viz., the subordinate and the insubordinate. The directive and positional perceptions of the sense of touch are subordinated to those of vision, as indicated in the following original experiment: Holding the thumb and forefinger midway between and a few inches before the eyes, let them be rubbed together. Looking now with both eyes at a remote and median position, two spectral thumbs and forefingers will be seen, and with these singular results: When the optical axes (still divergent) are inclined to the right side, the forefinger will feel the thumb at the site of the right spectrum; on inclining the axes leftwards, the thumb will be localized on the left side. The same tactile *abeysance* may be proved by studying one's face in a distorting mirror; however much the forehead is seen to recede abnormally, its parts will be accurately felt by the fingers just wheresoever they may be seen. Brewster's well-known experiment with the cane-chair,¹ in which the octagonal perforations of the seat are felt in a different position to which they are seen, does not invalidate the above statement; this is apparently an example of single vision, but really one of double vision with a sensorial antagonism operating between the ocular muscles. Is it possible that a tactile positional perception can be in *abeysance* to visual positional perceptions that are at variance so as to neutralize each other? Certainly not; in such an event, as a result of the first experiment, the thumb would be felt by the forefinger at the sites of both the visible spectra simultaneously.

Another example may be instanced in viewing objects behind by bending the body forwards and looking between the legs; the superior rectus now localizes objects below and the inferior rectus above, because these muscles are in *abeysance* to those bending the trunk. Muscular *abeysance* exhibits many manifestations in the upper extremity, concerning which it may be said generally that a given distal segment is subordinated to any given proximal segment—the fingers to the hand, the fingers or hand to the forearm, and this to movements of the arm. The index finger indicates direction or position only through the *abeysance* of the indicator muscle to wrist, elbow, or shoulder movements, which clearly modify its indications. Analogously taking a natural skeleton of the upper extremity, the phalanges may be moved independently of the metacarpal bones, but not *vice versa*; and the carpus may be moved independently of the humerus, but not *vice versa*. Hence a practical illustration is afforded of a statement made elsewhere that "the muscular organism of the secondary perceptions is correlated to the mechanical forces of nature in like manner as that of the primary perceptions is correlated to the sense essences of nature;" other facts endorsing the same doctrine are contained in the present thesis.

A single instance of insubordinate muscular *abeysance* must suffice—namely, it is the usual province of the right external rectus to give rise to a rightward perception; but, rotating the face over

¹ Brewster on the Stereoscope, p. 95, 1856.

the right shoulder, the resultant perception of this muscle is a backward one. In this experiment the rectus is not in abeyance to the rotatory muscles of head, but it co-operates with them, whilst remaining *per se* an efficient factor throughout. The result is due to an absence of inconsistency or antagonism between rightward and backward directive perceptions. A mechanical equivalent of the process is afforded by two rulers that are fixed end to end at right angles, and that rotate on the free extremity of one of the rulers as on a centre.

Derby-villas, Forest-hill, S.E.

A SIMPLIFIED EVACUATOR FOR LITHOLAPAXY.

By HENRY J. BIGELOW, M.D.,

Surgeon to the Massachusetts General Hospital, Emeritus Professor of Surgery in Harvard University.

THE operation for the immediate removal of a calculus through a catheter, like many other surgical operations, can be accomplished more or less satisfactorily by any one of several instruments which much resemble each other. But it can be done better by employing a more perfect apparatus than those now generally in use. It has been said that "no new form of instrument is required by this operation," which is true so far as it implies that neither a lithotrite nor an evacuator is a new instrument. But it would be a mistake to infer that the operation could have been done with the instruments of the old lithotrity, and that they had needed no change to adapt them to what is now required of them, or that they cannot be still further modified to advantage. The new operation cannot be performed with the old instruments. It requires a larger evacuating catheter than that of Clover, through which the usual product of the lithotrite could not pass, except powder and sand, and that only in limited quantities, because the other detritus obstructed the entrance of the tube.¹ Though at first received with a good deal of distrust, the large catheter has been finally adopted by all the surgeons who have done the operation, and in fact cannot be dispensed with. It should be combined with a thoroughly efficient aspirator; but no particular form of aspirator has so far met with general approval. Though better than it was, surgeons have none as yet which entirely satisfies all requirements of the operation, and is at the same time compact and convenient to handle, and simple in construction. This part of the evacuator still needs improvement.

¹ Sir Henry Thompson says (*Diseases of the Urinary Organs*; Philadelphia and London, 1882), "The evacuating catheter to be attached to the aspirator should be as large as the urethra will admit; usually No. 15 or 16 of the English scale [26 to 28½ French] may be used without any danger. Sometimes No. 17 or 18 [30 and 31 French] are admissible; but such sizes are quite unnecessary for small stones, and may produce mischief; hence they are only to be used where the presence of a large stone demands corresponding instruments." Or, it might be added, to expedite the operation, when the urethra is large and healthy. The size of the normal urethra, according to Otis, is, if we except the meatus, 32 of the French scale. Clover's evacuating catheter was 21. Those now in use range from 26 to 31. Care, however, and often special skill, may be required to introduce safely the largest sizes; 31 is very rarely needed, and the French sizes 28 and 29 are generally the most convenient. For a final washing or sounding without anesthesia when it is desirable to give the patient the least discomfort, even so small a calibre as 26 is sometimes useful. Through a catheter of this calibre Mr. Teevan has removed calculi weighing six or eight hundred grains; but such cases should be regarded as showing what is possible, rather than as establishing a rule of practice. Here I may add that although no lithotrite compares in size with the larger tubes, it is yet true that long-bladed lithotrites, especially if they have the sharp extremity of the old instruments, are more difficult than tubes to introduce with safety. Although since 1878 my lithotrites have been made in three sizes, I have rarely had occasion to employ any other than the middle size.

The usual parts of an evacuator, not including the catheter, are these:—

1. The exhaust, the best form of which is an elastic bulb.

2. A space or trap for air at the upper part of the instrument.

3. A glass receiver at the lower part, to collect and show the débris.

In drawing out fragments from the bladder through the large catheter, one bulb or aspirator, if strong enough, is about as efficient as another. An aspirator of almost any shape, and having almost any combination of its parts, will do this. So will a mere elastic bulb attached directly to the catheter, without joints or receiver, if it is placed lower than the catheter, bent down like the body of a retort, so that the fragments can fall to the bottom of it; and the instrument will still work well if it has joints made, for economy, of cork or rubber instead of metal. But, however otherwise arranged, a satisfactory aspirator should have—

4. Some device, near the catheter, to act as a trap for débris and secure every fragment that has passed it.

The chief difference among evacuators now is in the certainty with which they retain the fragments they have aspirated. Any instrument will draw out the fragments, but few hold them securely, for the débris do not always fall into the glass receiver, nor do they always remain in it. On the contrary, they are easily carried back to the bladder. This defect in the action of the evacuator has received little attention from surgeons, although it is the only point connected with the instrument which offers any difficulty whatever. Until recently it has been remedied only by sacrificing simplicity in the apparatus.

In endeavoring to make a satisfactory evacuator for litholapaxy, many experiments have to be tried. It is quite possible that a perfectly satisfactory instrument might have been contrived some time ago if it had been generally understood that an evacuator that works best with pieces of broken coal in a vessel of water will succeed best with the fragments in the bladder.² So also will the surgeon if he is otherwise well qualified. It is true that the living tissues are easily injured, but in other respects the experiment can be made sufficiently like the operation to give it great value. Aspirating débris from the bladder is not a question of pathology, but of operative surgery; of physics. And in view of the fact that we fail in some bladders to discover a last fragment even by repeated washing, an evacuator should be so constructed that it will absolutely prevent a fragment that has once passed the catheter from returning to the bladder to become the nucleus of another calculus.

It is not altogether easy to meet this requirement, because the solid particles are usually borne back and forth with the current of water. In a common evacuator, they are carried wherever it goes, first from the bladder to the bulb, and then, when it is reversed, back to the bladder, a part only falling into the receiver at each aspiration. As we may fairly assume that a surgeon would not deliberately inject foreign bodies into a patient's bladder, there must be something wrong in a system which obliges him to do this, and makes it necessary to aspirate the same débris twenty times over in order to remove it. In short the apparatus as commonly arranged is still a defective one, and needs some special contrivance to assist the action of gravity in securing the débris.

Surgeons have long felt this. The use of a long

² The specific gravity of hard coal is 1.575, that of a urate calculus is 1.540, and of a mulberry calculus 1.262.

elastic tube connected with the catheter has been more than once criticised, and with some reason, on the ground that it might contain fragments which would be returned to the bladder. And again, in order to shorten by an inch the route from the bladder, a less convenient stopcock has been substituted for the usual one. But lithotritists should be fully aware of the fact that whether there is an elastic tube or not, a tenfold greater quantity of fragments is generally driven back out of the bulb itself, and that the difficulty lies almost wholly in that part of the instrument. At each expansion débris are drawn from the bladder into the bulb, where they are detained until, when it is compressed, they are injected back into the bladder. Only a part of them, sometimes only the larger half, the quantity varying in different instruments, settle into the glass receiver. This important fact, so little recognized, should not be accepted without demonstration.

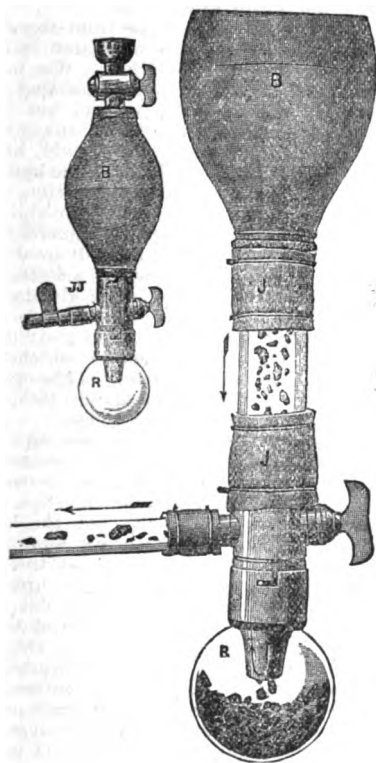

Fig. 1.

B, Bulb. R, Receiver. J J, A joint.—These two figures, representing the same instrument, are intended to illustrate the fact that all evacuators return fragments to the bladder unless provided with some especial arrangement to retain them. The joint J J of the smaller figure is opened in the larger figure to receive a glass tube. Through this fragments are seen as they are drawn into the bulb and expelled from it. The glass evacuating catheter shows them again, on their way to and from the bladder. The receiver R shows other fragments in the act of being lifted by the current and returned to the bladder.

An instrument which Sir Henry Thompson has lately abandoned (Fig. 1) can be made to demonstrate exactly how the currents act upon the fragments in an evacuator which is unprovided with a catheter-trap to prevent them from re-entering the catheter. It is here selected because the peculiar form of this instrument makes it easy to fit a glass tube to it, so that we can see what takes place in the interior. Let a piece of glass tube, an inch in

diameter, be inserted at the joint J J, between the bulb B and the catheter, to show what passes with the current from one to the other in either direction. If the end of the catheter be now placed in a suitable vessel of water containing fragments of coal of different sizes, while the bulb is alternately compressed and allowed to dilate, a continued stream of fragments will be seen rising from the vessel into the bulb, and then returning to the vessel, as they inevitably do to the bladder. The back-flow of débris can be still better watched if a glass tube be also substituted for the catheter, as in the figure.

But there is another important fact illustrated by this instrument. Fragments do not always stay in a receiver after they have been deposited there. When the glass receiver R of this evacuator is half filled with fragments, a part of these are easily carried back into the bladder or into the vessel. They are first lifted up from the receiver into the bulb, and then driven out through the catheter. For though the orifice of this glass receiver is small and protected by a special trap, the current and débris pass out of it as well as into it. It could not have been foreseen that fragments would escape from a receptacle apparently so well arranged. But it will be found that in any instrument, if the bulb or catheter directs the current into the glass receiver, whether directly or obliquely, fragments are easily carried out again.

And the general result is little better if, to avoid stirring the fragments which lie in the receiver, the current is directed horizontally over the mouth of it instead of into it. Some of them pass directly back and forth between the bladder and the bulb, over the receiver without falling into it. This defect can be shown in an instrument recently employed by Sir Henry at the suggestion of Weiss & Co., where the stream from the catheter passes horizontally through an empty chamber on its way to the bulb. As the stream enters it, its velocity is so diminished that fragments fall to the bottom into the receiver in greater number when the bulb is weak. Many fragments as usual are secured. But in order to be wholly effectual, the chamber intended to retard and break up the current by its size would have to be inconveniently large to give time to the floating débris entering on one side to settle into the receiver without passing further. The principle here involved is quite different from that of the evacuator represented in the above figure. This instrument is not unlike one formerly figured in *THE LANCET*, but the valve and strainer which there act as a trap have been omitted, and, in consequence, not a few fragments escape back to the bladder.

In Weiss's evacuator again, some of the fragments which enter the bulb gather in the bottom of it, which is lower than its outlet, and where there is no receiver to collect them. The chief difficulty, however, is not that these fragments stray into the bulb, but that for want of a trap they are afterwards liable to escape out of it to the bladder.

This difficulty is not wholly obviated by placing a strainer across the mouth of the bulb to prevent the fragments from entering it, as has been done in some other evacuators.

(To be Concluded.)

—A TOMBSTONE has, we are informed, been placed in Walmer churchyard over the grave of the late Fleet Surgeon William Anderson, by subscription amongst the officers of the Royal Navy and Royal Marines.

ST. GEORGE'S HOSPITAL.

SARCOMA OF THE FEMUR; AMPUTATION AT THE HIP-
JOINT; RECOVERY; NO RETURN OF THE DISEASE; RE-
MARKS.

(Under the care of Mr. PICK.)

The following case is interesting, not so much on account of the rarity of the disease, as from the fact that amputation of the hip-joint was performed for sarcoma of the lower end of the femur five years and a half ago, and the patient has remained well and free from any symptoms of a return of the disease up to the present time.

Mary Anne P—, aged nineteen, was admitted into Princess ward on Jan. 10th, 1877. Her history was as follows:—Her parents were both alive and healthy. She had three brothers and three sisters, all living and healthy. She stated that she had never been very strong, and had suffered from enlarged glands in the neck when a child. She had had measles in early life, but no other complaint, and had never been troubled with cough. She had been accustomed to live well and work hard. Catamenia had always been regular; no syphilitic history obtainable, and no history of cancer in the family. About four months previous to admission she noticed that the lower part of the right thigh began to swell, more particularly on the outer side. The right knee also swelled. About a month later the thigh and knee began to pain her very much, more especially when pressed upon, and when she moved. The swelling did not interfere with the motions of the knee-joint, and she was able to walk. She does not remember ever having received a blow or injury of any kind. The swelling did not increase rapidly after its first appearance. For some weeks she attended as an out-patient, and was treated with iodide of potassium. At first the treatment appeared to produce some benefit, the swelling got smaller and she gained weight and strength; but for a month previous to her admission the swelling increased rapidly, and she suffered from a dull, aching pain in the part, which was worse at night.

Upon admission she was found to be thin and slightly built, presenting the appearance of a strumous diathesis. There was a large, smooth and nearly uniform swelling situated at the outer side of the lower end of the femur, of the right side, about two inches above the condyle. The swelling was confined to the outer side of the shaft of the bone, on the inner side and at its lower extremity the femur could be felt to be unaffected. The skin was tense and reddened, but freely movable over the tumour, and some enlarged veins could be seen crossing over it. The swelling was hard and somewhat elastic and firmly connected to the bone, from which it could not be moved. Pressure caused pain, but no sensation of crackling or fluctuation could be felt. Now and again she experienced a starting or shooting pain through the limb. Upon placing a stethoscope on the

outer and lower part of the swelling an occasional soft, blowing bruit was audible. The bruit was not constant, and could only be heard at one particular part of the tumour. At this spot, upon making firm pressure, an indistinct feeling of pulsation could be perceived. This pulsation and bruit were felt and heard for the first time on the day after admission, though they had been carefully sought for on several previous occasions. The temperature of the affected limb, especially over the swelling, felt considerably raised above that of the sound limb. There was some enlargement of the glands in the right groin, but the same condition also existed on the left side. The knee-joint was unaffected and could be flexed, extended, and rotated with perfect freedom.

A consultation was held, and it was determined to remove the limb. This was proposed to the patient, but she refused to entertain the proposition and left the hospital. She was lost sight of for a time, but again applied for readmission on March 12th, six or seven weeks from the date of her previous discharge. The alteration in her appearance was now most marked. She had lost flesh considerably and was much emaciated. There was a hectic flush on her cheeks, and her countenance wore an expression of great anxiety. She was unable to sleep on account of pain, and had entirely lost her appetite. The tumour had grown rapidly, especially in an upward direction, so that the upper margin, which was well defined, reached to within six inches of Poupart's ligament. The skin over it was red, shining, and adherent to the surface of the swelling. There was a distinct pulsation and an audible bruit. The glands in the groin were more enlarged. Amputation at the hip-joint was now proposed to the patient, who willingly accepted any proceeding which would relieve her of her intense pain. This operation was accordingly performed on March 15th by the long anterior and short posterior flap.

The subsequent progress of the case requires no comment. Her recovery was much retarded by the formation of bed-sores, the profuse discharge from which at one time threatened her life. Eventually, however, she rallied and left the hospital with a perfectly sound stump. Six months after the operation a patch of dulness about the size of the palm of the hand appeared at the upper part of the right chest, accompanied by tubular breathing in this situation, and it was found that the disease was returning in the lungs. Gradually, however, it disappeared, resonance returned, and the breath sounds again became natural. The exact cause of it was never clearly made out. At the present time (November, 1882), five years and a half since the operation, the patient is perfectly well, and there are no signs of a return of the disease. She has married, and expects shortly to become a mother.

The tumour after removal was found to be of a soft brain-like consistence and of an almost uniform greyish-white color. Interspersed throughout its structure were numerous patches of extravasated blood. The tissue of the tumour was arranged in lobules, each of which was surrounded by a more or less distinct capsule. The whole of the lower third of the femur was destroyed and its structure replaced by the growth, which had also extended downwards into the knee-joint. The patella and bones of the leg were unaffected. The microscopical appearances were as follows:—A number of thickly interlacing spindle cells, with distinct nuclei, arranged for the most part in closely set parallel bundles. Intermixed with these spindle cells were a number of irregularly, round, nucleated cells, and in some parts the tumour consisted wholly of these. They were

grouped in a delicate stroma, were irregular in shape, and contained two or three nuclei. In addition to these, there were found, here and there, large, irregularly round, multi-nucleated cells, not unlike transparent "giant cells."

Remarks.—The disease in this case appears to have belonged to the class of central tumours of bone, in contradistinction to the subperiosteal form of growth; and, as Mr. Butlin has pointed out in his Lectures at the College of Surgeons, the "treatment of central sarcoma of the femur is very much more hopeful than of subperiosteal sarcoma. That amputation high up at an early period of the disease may be undertaken with very fair prospect of success, if not of permanent recovery, at least of long relief." This case seems to bear out Mr. Butlin's opinion. Nothing could have been more unpromising at the time of the operation; the rapid growth of the tumour and the considerable emaciation which had taken place during the six weeks or two months immediately preceding it induced us to regard the case as one of a very malignant type, and to give a most unfavorable prognosis. Happily, that opinion has not been verified by the subsequent history of the case.

NEWCASTLE-ON-TYNE INFIRMARY.

GASTROSTOMY IN A CASE OF MALIGNANT STRICTURE OF THE OESOPHAGUS; REMARKS.

(Under the care of Dr. G. H. HUMK.)

J. H.—, a laborer, aged fifty-seven, was admitted on August 3rd. Twelve months previously he had first found difficulty in swallowing, and had cough and shortness of breath. He had attended at the infirmary as an out-patient from time to time, and had bougies passed, which temporarily relieved the difficulty in swallowing. At the time of his admission he could only swallow liquids. Examination of the chest detected some dulness to the left of the sterno-clavicular articulation, and throughout the lungs a considerable amount of bronchial catarrh. An oesophagus bougie could be passed down to, but not through, a stricture situated nearly opposite the middle of the sternum. For a time after his admission a considerable amount of liquid food was taken, and, with rest in bed, the patient's condition appeared slightly to improve. But the difficulty in swallowing gradually increased, until very little could be taken by the mouth, and life was maintained almost solely by nutrient enemata. Gastrostomy was therefore determined upon; and the first stage of the operation was performed on Sept. 2nd. An incision, about three inches in length, was made an inch from the left costal margin, its direction being such as to make it terminate at the extremity of the tenth rib. The structures of the abdominal wall being divided down to the peritoneum, all bleeding was completely stopped, and the peritoneum divided on a director. The wall of the stomach, which was readily found lying below the left lobe of the liver, was taken up between the finger and thumb, and a silk thread passed through it for the purpose of holding it forward during the insertion of the sutures. These latter were nine in number, and enclosed a piece of the gastric wall, somewhat larger than a shilling. The sutures were passed into, but not through, the wall, so that they did not enter the stomach cavity; and each was passed through all the structures of the abdominal wall, so as to bring the visceral in apposition with the parietal peritoneum. The ends of the incision in the abdominal wall were then brought together.

The operation was performed under carbolic spray. During part of the operation ether was un-

fortunately administered instead of chloroform, and it was probably in part due to this that on the evening of the day of operation the pulmonary catarrh was considerably increased.

Sept. 3rd: Catarrh much increased, though the patient had a good night. Temperature 100° F.; pulse 86. The enemata were continued, and use was also made of Slinger's nutrient suppositories.—5th: Great thirst and hunger complained of; breathing, which has been very bad, is somewhat relieved. Temperature 99°; pulse 82.—6th: On removing the dressings the exposed portion of the stomach wall was found covered with lymph, and firm union seemed to have taken place to the edge of the incision. The stomach was therefore opened with a tenotomy knife, the incision being just large enough to admit easily a No. 10 gum elastic catheter. Some milk was poured into the stomach by means of a funnel and tube attached to the catheter. Feeding with milk and brandy and beef-tea was continued from this time at regular intervals, and the enemata were administered as before.—7th: The patient has had a good night. Temperature 99°; pulse 80.—9th: The difficulty of breathing, which had become less distressing, has again increased, and there is now a dusky appearance of the face. There is slight wandering.—13th: The patient died.

Post-mortem examination.—The body was much emaciated; the left lung was consolidated, especially the lower lobe, and gangrenous in parts. Similar gangrenous masses were scattered through the right lung also, but were less numerous. Opposite the fourth dorsal vertebra the oesophagus was found to be constricted by an annular deposit in its wall of a scirrhus nature. This constricting ring was almost an inch in longitudinal depth. The stomach was adherent to the margin of the incision, and there was not the slightest trace of inflammation either on the peritoneum or wall of the stomach.

Remarks.—This case was, undoubtedly, in some respects, a favorable one for gastrostomy. The cancerous formation in the wall of the oesophagus was of limited extent, and had not involved surrounding structures. Probably a lengthened period might have elapsed before life was threatened by the invasion of the air-passages and large vessels. It is a matter of regret, therefore, that the operation was not performed earlier, before the patient's strength had become exhausted, and the consequent condition of the lungs developed. The operation in itself does not appear to be attended by special danger. When peritoneal surfaces are placed in accurate contact they speedily unite, so that the general cavity is shut off, and there is little risk of discharge entering it from the wound. The case only serves to illustrate the well-recognized truth that gastrostomy to be of service in prolonging life must be had recourse to in good time.

LOCOMOTOR ATAXIA; SEVERE LIGHTNING PAINS; LEFT SCIATIC STRETCHED; MARKED RELIEF.

(Under the care of Dr. DRUMMOND and Mr. PAGE.)

For the following notes we are indebted to Mr. James Limont, senior house-surgeon.

R. R.—, aged twenty-three, a fisherman, was admitted for shooting pains in the legs and staggering gait. The patient stated that he had been greatly exposed to cold and wet during the past eleven years, and that he had frequently slept in trousers saturated with salt water. His habits had been very intemperate, and he had suffered from syphilis. In the summer of 1881, seven months before admission, he began to complain of pains in both legs, especially the left; subse-

quently he lost power in the lower extremities, and failed to control their movements properly.

As regards his family history, it may be stated his mother died twelve years ago of a tumour in the brain; one sister died of consumption. The father is still living and healthy.

On admission the man exhibited the typical features of locomotor ataxia. The ataxic gait was most characteristic; he staggered and fell whenever he attempted to walk with closed eyes, and was quite unable to stand when the eyes were shut, even though the feet were widely separated. He complained bitterly of the lightning pains, and had the girdle sensation well-marked. Analgesia was present in patches, and retarded sensibility was very marked in the legs (occasionally twenty-three seconds elapsed before a prick of a pin was discovered). The superficial skin reflexes and the knee-jerk were entirely absent. His sight was dim, the ophthalmoscope revealing pronounced syphilitic choroiditis.

On March 7th, about five weeks after admission, as the pains still continued very severe, Mr. Page cut down upon and stretched the left sciatic nerve. The operation was done antiseptically.—On the 15th the wound was entirely healed, and the patient expressed himself as greatly relieved of the pains in the left leg.—On the 30th he left the hospital quite relieved of the pains in both legs, but in no other way changed.

GUY'S HOSPITAL.

CASES OF ACUTE NECROSIS.

(Under the care of Mr. BRYANT.)

CASE 1 (from notes taken by Mr. Tresidder), *Multiple Necrosis, after Scarlet Fever, of Clavicle, Tibia, and Ulna; Sequestrotomy; Cure.*—John S—, aged three, was admitted on May 21st, 1881, into Lydia ward. He was the youngest of eight children, none of whom, except himself, had enlargements of the bones, and he had been always a healthy child until four months before admission, when he had scarlet fever with dropsy, and he had not since been quite well. First an abscess formed over the right tibia, and was opened; then, five weeks before admission, an abscess formed on the right clavicle, and two weeks later another on the left ulna.

On admission the sternal end of the clavicle was much thickened for an inch and a half. There was a sinus covered over with a scab, from which a thick creamy pus exuded, and the sterno-clavicular joint was diseased. Just below the bone there was an irregular lobulated mass, like a piece of fat, under the skin. The right tibia was much thickened throughout the whole diaphysis, and the dead shaft was felt through three places. The left ulna was also thickened, and there were sinuses leading to diseased bone.

On June 3rd the wound over the tibia was enlarged, and a thick layer of new bone was cut through, and a larger sequestrum, about three inches long, was removed, besides several pieces; in fact, nearly the whole of the shaft of the bone. From the lower end of the wound a piece an inch long, including the whole thickness of the bone, as well as the epiphysal end of the shaft, was removed.

The child improved much in condition, and in a fortnight the wound was almost healed; but a few small spicules of bone came away.

On July 30th, under an anæsthetic, the sinus over the ulna was enlarged, and a sequestrum comprising the greater part of the diaphysis was removed. The necrosed clavicle was also taken away.

On August 27th the wound over the clavicle was quite healed, and on September 12th the wound over tibia was almost healed. There was good movement in the ankle, and no pain in the swelling here.

On November 28th general health was fair. The wound over tibia was still not quite healed. Recommended to go out and return if any unfavorable symptoms came on.

On January 9th, 1882, the tibia wound apparently closed.

On June 1st the child was seen by Mr. Bryant, when all the bones were quite sound. The perished shell of bone in each case had contracted to its normal dimensions.

CASE 2. (From notes taken by Mr. Wilson). *Acute Necrosis of Upper End of Tibia; Suppurating Knee-joint; Sequestrotomy; Incision of Joint; Healing.*—Fredk. W—, aged eighteen years, a carman, was admitted on Feb. 27th, 1881. About three weeks before admission he knocked his left leg against a cart-wheel.

On admission there was an abscess over the inner tuberosity of the tibia and above the tubercle. There was some fullness of the capsule of the joint, and the lower third of the femur felt larger than on the other side, but there was no tenderness.

On February 24th the abscess was opened and a large quantity of pus mixed with blood exuded, and next day a back splint was put on.

On March 9th an incision was made on the inner side of the joint, and a week later, under an anæsthetic, and after an Esmarch's bandage had been applied, an incision was made and several pieces of necrosed bone were removed. There was acute suppuration of the head of the tibia and an abscess cavity in the head of the bone. Free incisions were made to ensure free drainage, and the leg put upon a back splint. The patient passed a good night after the operation, and the wounds began to heal at once.

On April 9th an incision was made just below the inner tuberosity of the tibia, and a large quantity of offensive pus let out.

The wounds have progressed favorably towards healing. The wound was probed, and a small fragment of necrosed bone was detected on July 27th.

On August 5th a Thomas's splint was applied.

Two small splinters of bone were removed on August 9th, and by November 16th several small pieces of bone had come away. Two sinuses remained unhealed. The patient left, and was to report himself in about a month's time.

SEAMEN'S HOSPITAL, GREENWICH.

CARDIAC DISEASE; PROLONGED INTERMISSIONS OF CARDIAC ACTION; ANTE-MORTEM CLOT IN HEART AND AORTA.

(Under the care of Drs. CURNOW and HALE WHITE.)

JOSEPH B—, aged forty-two, was admitted on July 11th, 1882, with a history of pain in the left side occasionally for two months, shortness of breath, and slight hæmoptysis. He had had rheumatic fever eleven years before. On admission the heart's apex beat was found in the fifth space outside the nipple-line. A double aortic murmur was present as well as a mitral systolic at the apex, with occasionally a presystolic also. The second sound was ringing at the base and the pulse collapsing. He left the hospital on July 25th, much improved. On Sept. 29th he was readmitted, under Dr. Hale White, complaining, in addition to his former symptoms, of frequent faints. The cardiac action was now found to be very slow, though

variable (usually about forty per minute). Physical examination gave a result similar to that previously obtained, but the murmur antecedent to the systolic was now more marked and persistent. It seemed also to vary in its position in time in the cardiac rhythm; when the heart's action was very slow indeed the murmur appeared to occur in the middle of the interval between the cessation of the second sound and the commencement of the first, a distinct interval elapsing between its termination and the systolic sound; on the other hand, when the action became more frequent, the murmur was heard immediately before the systolic sound and running right up to it; occasionally when the heart began to quicken, it even seemed possible to hear both these murmurs at once, a very slight interval separating the one from the other. The patient was subject to frequent transient attacks of syncope, which caused him much distress. On the morning of October 7th, these attacks occurred with greatly increased frequency, and about 9 A. M. he presented the following symptoms:—For the first three-quarters of each minute the heart beat strongly and regularly, about thirty-three times, and then ceased abruptly and entirely for a quarter of a minute when its action again commenced, to repeat the same course as before, each cycle of action and intermission occupying a second or two over the actual minute. When the heart stopped, the face at once began to grow paler and paler, the respiration became slow, deep, and sighing, with occasional low murmurs of distress; towards the close of the period of cessation of cardiac action, the pupils (always rather large) became widely dilated, then the eyelids dropped, the muscles of mouth and hands began to twitch, and the head fell back, and then just when it seemed death must occur the heart recommenced its slow measured action. With the first beat the face began to flush, but the twitchings of mouth and hands did not cease until the fourth or fifth beat, when also the eyes opened, the head was lifted and the patient seemed as it were to return to life. Between the periods of intermission he was quite conscious, and dreaded the moment when, as he said, his heart would "pull" within his chest, and he would lose his senses completely. When visited half-an-hour later the attacks had passed off, and from that time till October 10th, when he died, they only occurred at irregular and infrequent intervals. The treatment consisted in the administration of stimulants—viz., alcohol, ether and ammonia, but during the thirty-six hours previous to the morning of October 7th, he was taking in addition five-minim doses of tincture of digitalis every four hours.

Necropsy.—Heart of rounded shape with much hypertrophy and dilatation of both sides, weight $19\frac{1}{2}$ oz. Much atheroma and general dilatation of the ascending aorta, this condition extending quite down to the aortic orifice which measured nearly 4 in. in circumference. The aortic valves showed slight thickening and small calcareous nodules at their angles of junction. Immediately below the aortic orifice the wall of the ventricular septum presented a depression of $2\frac{1}{2}$ in. from side to side, and $1\frac{1}{2}$ in. from above down, the base of the hollow being formed by a fibrous membrane placed on a level with the inner lining of the right ventricle, but not bulging at all into that cavity. From the apex, where its base lay entangled among the columnæ carneæ, a large clot extended up into the aorta nearly to the top of the ascending arch. The base presented the usual pale yellow color, and elastic, homogeneous texture of a clot formed just before death; on tracing it upwards that part lying near the aortic orifice became much tougher,

darker in color, and more fibrous, while beyond the valves, the part lying in the aorta was shrunken, flattened, brownish in color, and when incised displayed a cavity full of dark grumous-looking matter with fibrous-looking walls. The clot had all the appearance of having been formed by accretion to the base, while the head became gradually more and more prolonged from its original place of formation at the apex of the left ventricle, so as ultimately to lie in the cavity of the aorta. Notwithstanding the presence of the murmur described above as to all appearance presystolic, the mitral orifice did not seem at all contracted.

TRANSIENT RIGHT HEMIPLEGIA FROM INJURY TO THE HEAD.

(Under the care of Mr. G. R. TURNER.)

For the following notes we are indebted to Mr. E. Penny, house-surgeon:—

Maude M—, aged two years, was brought to the hospital on August 7th, 1882, at 8.30 P.M., with the following history:—At 5 P.M. on the same day she fell off the table, striking the left side of the head with some violence as she fell. She did not complain of feeling any uneasiness until 6 P.M., when she became steadily but rapidly unconscious. Soon afterwards she was seized with convulsive movements of her right arm, right leg, and right side of the face. These occurred every few seconds. When brought to the hospital she had been in this condition an hour and a half.

On admission she was quite unconscious, and could not be roused in any way. Every few seconds she was seized with violent convulsive movements of the right arm, the right leg, and the right side of the face. Both pupils were dilated and insensible to light, but the right was larger than the left. Both eyes were turned to the left side, but the head was quite natural. Her pulse was 60, and very good; respiration 29, deep, but no difficulty about it; temperature 100° F. There had been no vomiting. Her head was examined, and a swelling found over the anterior and inferior part of the left parietal bone, but there was no evidence of any fracture. She was put to bed and an ice bag applied about 10 P.M.; the right arm and leg ceased their convulsive movements, and in the course of a few minutes were completely paralyzed, and the side of the face dropped. Her urine was passed in bed from time to time. Her temperature was now 98.4° ; pulse and breathing unchanged. About 1 A.M. she was noticed to move both right arm and leg, and from this time the paralysis gradually passed off, the face resuming its normal look last of all, and the leg recovering first. At eight o'clock in the morning she vomited freely, and almost immediately afterwards she recognized her mother. From this time she rapidly recovered, and left the hospital quite well in four days.

STROUD GENERAL HOSPITAL.

OVARIOTOMY DURING PREGNANCY; SUBSEQUENT NORMAL PARTURITION.

(Under the care of Mr. STORRY.)

For the following notes we are indebted to Mr. R. D. Cameron, resident medical officer:—

Emily B—, aged thirty, married, four children, was admitted on April 1st, 1882, with an ovarian tumour, the swelling of which she had noticed eighteen months ago. She last menstruated in January, 1882. Being incapacitated from following her household duties, and having lately suffered considerable pain in her abdomen, on the 11th of April (believing her to be pregnant), she

was placed under the influence of ether. Mr. Storry, with the assistance of his colleagues, and with the ordinary carbolic spray, opened the abdomen, torsioned one vessel in the abdominal walls, but found no adhesions. He then tapped one large cyst and one small one, tied the pedicle with chromicized catgut, and removed the growth. The uterus was found to be enlarged in the pelvis. The wound was brought together with chromicized catgut sutures. An india-rubber drainage-tube was left hanging from the lower part of the wound, and communicating at the other end with the abdominal cavity, and the usual gauze dressing and india-rubber bandage were applied. Eight hours after the operation two drachms of blood-clot were removed with a syringe from the drainage-tube. The tube itself was removed on the fourth day. The temperature in the axilla was taken every two hours for the first week and it never rose above 99°.

The patient was catheterized every six hours for the first week. The bowels were opened by an enema on the eighth day after the operation. On the fourteenth day she was sitting in an arm-chair, and a fortnight after this she returned home to her friends.

On Oct. 18th Mr. Storry delivered her of a fine female child.

GUEST HOSPITAL, DUDLEY.

CASE OF LIGATURE OF THE LEFT COMMON CAROTID ARTERY FOR HÆMORRHAGE.

(Under the care of Mr. M. E. MESSITER.)

THE following case is similar in its history and results to the one that was shown at the Clinical Society last October by Mr. Pepper.

R. R—, aged twenty-four, was admitted on Oct. 20th, 1882. On Oct. 11th he caught cold, and the left tonsil was found enlarged and inflamed; no swelling was visible externally, but during the two or three following days a fulness simulating mumps was observed on the left side of the neck and under the jaw, extending as far up as the mastoid process, but closure of the jaws prevented examination of the inside of the mouth and fauces.—Oct. 15th: Without any warning, profuse arterial hæmorrhage, to the extent of three pints, came on; his voice, hoarse previous to the hæmorrhage, now became subdued to a soft whisper; the lips and conjunctivæ were blanched. Pulse 80, compressible. He complained of a feeling of suffocation, but the syncope was not alarming. It was noticed that the tumour in the submaxillary region disappeared completely after the hæmorrhage. Patient said that the blood appeared to come from the back of the left ear. Cough did not precede the hæmorrhage, and the blood was not mixed with pus or air; it was arterial, and formed a firm clot. For twenty hours after this the patient seemed convalescent, when another swelling in the exact site of the last was noticed, which, in two or three hours, was dispersed by a second hæmorrhage to the extent of two pints of arterial blood; the syncope was greater than before, and the patient was thought to be moribund; he rallied, however. On the 19th hæmorrhage again occurred, and he consented at last to be moved into the hospital.

After consultation with his colleague, Dr. T. E. Underhill, Mr. Messiter ligatured the left common carotid above the crossing of the omohyoid. Antiseptic precautions were observed. Catgut ligature was used, and cut short off. Two minutes after the vessel was ligatured there was facial paralysis on the affected side, but it passed off in two hours.

The man went on well until Oct. 26th, when he had a severe rigor, and a temperature of 105° F.,

and his evening temperature came down a degree each evening until October 31st, when it stood at 100° F.

On Nov. 8th he had a similar attack, with a temperature of 103° F. These attacks may have been caused by some slight septicæmia. His general condition, however, was fairly satisfactory all through; the wound looked healthy all the time; he had no swelling near it, no discharge of collected pus, and no hæmorrhage. The only symptoms that occurred in connection with the high temperature were weakness and sweating.—17th: Wound nearly healed, and the patient allowed to get up. He had gained in flesh since entering the hospital, and looked anything but anæmic. His mental condition was good. There was no headache, nor swelling about the neck or side of the jaw. The left carotid pulsated up to the point of the ligature, but hardly perceptibly on the other side. There was no pulsation in the facial artery of the affected side, and it was but slight in the left temporal. There was no paralysis or loss of sensation. A loud double aortic murmur existed, which did not exist when he was taken ill, and on his admission into the hospital only a faint aortic obstructive bruit was found.

Remarks.—I may add that the common carotid was chosen as the vessel to place the ligature upon, as it was thought that the close proximity of so many large branches would make it unsafe to ligature the external carotid. I fail to see how a distance of a quarter of an inch even could be obtained free from branches on the latter vessel, whereas the absence of all branches makes the common carotid so peculiarly the vessel to apply a ligature to.

ST. BARTHOLOMEW'S HOSPITAL.

THREE CASES OF ACUTE RHEUMATISM COMPLICATED WITH PERICARDITIS AND PLEURO-PNEUMONIA; REMARKS.

(Under the care of Dr. SOUTHEY.)

THE following notes and remarks illustrate the supervention of some grave complications in acute rheumatism:—

CASE 1.—Letitia T—, aged sixteen, a machinist, single, an anæmic strumous-looking girl, was admitted on Oct. 5th with rheumatism and pericarditis, having been laid up at home with articular rheumatism since September 28th (eight days). This was the first attack of rheumatism she had had, and with the exception of scarlet fever and whooping cough she had never been laid up before.

Condition on admission.—Perspiring profusely; temperature 102.6°. Decubitus dorsal; no pain in chest, no cough; she lay very still quite low in bed; mind clear. Tongue white and furred; breath foul; bowels costive. Micturition natural, urine high colored, otherwiser normal. Catamenia just ceased, always regular. Heart apex beat in the fifth interspace below the nipple. Thrill felt with systole, and friction rub heard all over the cardiac region. Pulse 144, soft. Lungs presented no abnormal sounds or dullness. Respiratory sounds clear; respiration 90. Abdomen natural. Large joints, as shoulders, hips, and knees, were more affected than the small ones.

Treatment by twenty grains of salicylate of soda, and seven drops of tincture of opium every four hours. The temperature fell the following morning to 98.6°, and only rose to 100.2° on that and the next day. Her pains promptly subsided. There was no anxiety; no restlessness. On the thirteenth day of the rheumatism the temperature fell to normal and remained so for three days, but the

friction rub became less distinct, and the præcordial dullness increased. She was very drowsy, but woke up to take her nourishment. The opiate was now diminished, and the salicylate given less frequently. There was effusion enough to produce marked præcordial dullness on the twelfth day of illness, and contemporaneously, or nearly so, bronchial breathing and bronchophony were noticed at the root of the right lung, and over more than two-thirds of the left lung. The dorsal position was maintained. Temperature 102.6°; pulse 120. Symptoms of more active implication of the left pleura were noticed on the nineteenth and twentieth days of the illness. Pain stitchlike and friction rub. At the same date the dislocation of the heart's apex upwards and outwards, and its disappearance from the chest-wall, too, were well marked. The heart's impulse being felt on the level of the mammae, she was advised to make some effort herself to lie on both sides alternately, and was directed to be propped by pillows into such position. Slight ægophony was noticed over the area of bronchial breathing.

Treatment.—Twenty grains of salicylate of soda, and five drops of tincture of opium, every four hours, were repeated. Her temperature fell gradually from the nineteenth day of illness, and her pulse improved. She has been able to sit up in bed and do needlework. Since the twenty-fourth day her pulse has been from 74 to 84; respiration 24; and temperature below normal. Heart-sounds have been clear, and no friction sound has been heard over front of chest. She has had no fever and no cough, but there is still a friction sound synchronous with respiration behind over left lung, some dullness and evidence of feeble air entry at base of lower third of left lung. She entered upon convalescence on the twenty-fourth day of her illness.

The facts in evidence of the course of this patient's disease are:—Pericarditis; pericardial effusion; imperfect air entry into lower lobe of left lung. Bronchial breathing; no rusty expectoration, followed by lateral and posterior friction rub and slight ægophony; rheumatic pleuro-pneumonia, with slight pleuritic effusion. Her temperature fell from 102.6° to 99.4° on the ninth day of her illness, pericarditis notwithstanding, and it was not till ten days later that it rose at all high again, 100.6° and 101°, when she had some fever from her left pleuro-pneumonia. This febrile disturbance lasted four days, and she has since convalesced with one slight relapse.

CASE 2.—Eliza P—, aged forty-six, and fairly nourished, prematurely grey-haired woman, single, entered on her menopause at the age forty-one. She had small-pox at nine years old, and her first attack of rheumatism at nineteen, which laid her up for some weeks; second attack at the age of forty-five, during which she was laid up six weeks. The present illness began three weeks before her admission by swelling and pain in her left foot, which shifted to her shoulders, calves, knees, and lastly wrists. She was feverish, had no appetite, and the pain made her feel sick.

Condition on admission.—Sept. 9th: Lying flat on her back, unable to help herself; all the joints of her arms stiff and painful; both wrists swollen; the right red and very tender. Knees and right hip-joint very painful; ankles swollen, red, and hot to feel. Pulse 108; respiration 18; temperature 100° to 101°. Bowels open four times freely; tongue coated with usual thick white fur, and inclined to dry; urine high-colored; skin moist; pupils large.

Physical examination.—Fauces and abdomen yielded negative signs; heart impulse feeble, apex beat indistinguishable, systolic apex murmur;

præcordial dullness increased over both lungs before and behind; rhonchus and catarrhal sounds, but resonance unimpaired. She was placed on the usual slop dietary, and treatment by salicylate of soda was pushed to salicylism, an event established in twenty-four hours.

Course and progress.—Three days later her pains were gone; but she complained much of her head, and her cough was troublesome. She took her nourishment fairly, but slept very little. Pulse 78, small and weak; respiration 20. Good resonance over lungs, front and back, and fewer moist sounds. Joints still swollen, and painful upon least movement. General condition extreme weakness; lies always in the same posture. After she had been under treatment twelve days, and therefore on about the thirty-third of her illness, we noticed that her pulse had risen to 96, respiration to 36, and temperature, which had gradually fallen to below normal, rose to 100.5°. Her cough was more troublesome, and she had a relapse of pains. Pericardial friction was now audible all over the cardiac region in front, and the dullness increasing. The following day the effusion was obviously increased and her temperature went up to 104°, but no physical signs as yet of pressure upon the lungs were observed. The relapse of pains lasted for the usual three days; improved on the fourth, when she slept well without any opiate. But we observed marked dullness on percussion on this the thirty-seventh day of her illness at the base of the left lung. Pericardial friction and præcordial dullness still well marked in front. Since her pericarditis had been ascertained beyond doubt she had taken repeated moderate doses of morphia, and was propped up in bed. The following day fine pneumonic crepitation could be heard over the dull area of her left lung, with bronchial breathing, transmitted also to the right lung. The color of the sputum was distinctly rusty. Meantime, notwithstanding the pneumonic complication, the temperature fell to nearly normal. Three days later both legs were anasarctous, and pitted widely. Stimulants had been given, but were now increased. Two days later improvement commenced, and gradually the dullness receded, and more air entered the affected lung; but her cough, she said, "tore her to pieces." Pulse 96; respiration 42. Her improvement steadily went on; the cough subsided, and she was free from all pain on the forty-eighth day, on which she was able to wash herself.

On the fiftieth day the pericardial friction gradually disappeared, but a pleural rub remained at the left base, and in the left lower lateral region for some days longer. She got up for a short time a few days ago, the sixty-sixth day of her disease.

In this case again there was pleuro-pneumonia of the middle or lower portion of the left lung occurring shortly after the evidence of a considerable pericardial effusion has been established. Yet it ran a favorable—nay, more, a speedy—course to entire resolution, so that in a fortnight or three weeks afterwards the woman was convalescent.

CASE 3.—Emma W—, aged nine, a poorly nourished strumous child, with dark hair and pasty anæmic look, was admitted into Faith ward on October 3rd, suffering with acute articular rheumatism and pains in her chest. Her illness had lasted a week, and the pains and swelling had begun in her right hand.

Condition on admission.—Temperature 102.6°; skin hot and moist; cervical glands enlarged. Tongue moist, but furred; abdomen nil; bowels confined; urine scanty. Chief seat of pain and rheumatic inflammation in left hip-joint. Pulse 112; respiration 33.

Physical examination.—Heart's apex in fifth interspace outside the left nipple, systolic murmur at apex; pericardial friction at base; præcordial dullness scarcely increased abnormally. Lungs: no morbid sounds, but enfeebled vesicular sounds, and slight dullness at both bases behind, and laterally, over the right. She was treated with salicylate, and for four days went on remarkably well; her temperature fell to below normal, and pericarditis and endocarditis notwithstanding, she had four days' intermission of her fever; but then her temperature gradually rose, in forty-eight hours, from 97° to 100·6°; pulse 108. The pain in her heart region was greatly increased, and the præcordial dullness increased also, showing no inconsiderable pericardial effusion, extending all across the chest in front, and well up into the left axilla. She had to be propped up in bed to get her breath, and we recognized dullness, with bronchial breathing, all over the middle portion of the left lung; posteriorly in scapular, interscapular, and subscapular region, also across the root of the right lung. The cardiac region was painted with iodine and poulticed, and some morphia was given in small doses, 1-24th of a grain every four hours. For four days she was extremely ill, then suddenly began to improve. Her temperature fell to 99°; her skin acted, and her pulse was 108; tongue moist and clearing. Dullness on percussion; bronchial breathing, and bronchophony still marked the area of the left lung consolidation; but there was no redux crepitation, and no expectoration, and very little cough.

Again the mode of recovery was in the order which I have exactly observed—namely, that as the præcordial dullness diminished and the effusion was reabsorbed, so the lung consolidation lessened, and air re-entered it, with here and there a little bronchial crepitation; on the twenty-eighth day of her illness, having had no further elevation of temperature or increase of rheumatic pains, sleeping and eating well, the pericardial friction rub became re-established all over the chest in front. Breathing sounds were faintly heard over the area of previous lung consolidation, and she steadily convalesced. Yesterday, however, and for the last week, we have been able to recognize a distinct pleuritic friction sound over the left lung base.

Remarks by Dr. SOUTHEY.—I have taken three cases of pericarditis that had well-marked pericardial effusion; no rare, no exceptional cases, but all illustrating a rule so invariable in my experience that I have often wondered it should have escaped comment—the association of pericardial effusion with pneumonia of the lower lobe of the left lung, or with pneumonia of the middle symmetrical portions of both lungs. In slight pericardial effusion this complication is not met with; in large effusion it is invariable. The left lung is that which is always first and most involved. Is it an effect of pressure? Is it a consequence of dorsal decubitus? Is it a result of the filling up of the posterior mediastinum and that complementary space into which the lung ought to be expanded in the inspiratory augmentation of the thoracic chamber? I believe the latter explanation is the correct one, because the order of physical signs is so very regular. Increased præcordial dullness in front, absence of respiratory sound first between the lower angle of the left scapula and the spine, then dullness on percussion over the same area. The affair terminates in some cases with nothing more than inexpansion of the lung; there is superadded no bronchial breathing, while in others bronchial breathing is well marked. And in some of these, again, the morbid process advances no further; effusion into air cells and

solidification of lung tissue are all; a little friction rub follows, but no rusty expectoration, no attendant bronchitis, no fine or redux crepitation; while a third degree of the same lung disease may occur, as in E. P.'s case, attended by both rusty expectoration and fine crepitation and redux crepitation, in other cases where the pericardial effusion is of longer duration or slower absorption. I do not remember to have ever found this pneumonic rheumatic complication independently of pericardial effusion, although I have seen repeated examples of slight superficial rheumatic pericarditis which were not thus complicated. This rheumatic pneumonia has a far more favorable prognosis than either its extent or occasional doubleness would at first thought entitle it to. If my theory of its causation be correct, the treatment I adopted in the three cases I have brought before you, and which experience has taught me is good, is also rational—viz., subduing the joint pains by opium, so that the patient may be moved into a less dorsal position; propping up of the patient by pillows; and administration of stimulants. Rheumatic pericarditis and rheumatic pneumonia, or pleuropneumonia are doubtless attended seldom nowadays by a fatal issue, but when bleeding and mercury were principally relied upon for conducting these local inflammations to resolution, and even in the time when alkalies were chiefly trusted to in the treatment of rheumatism, death was far from being uncommon. That the lesser mortality of rheumatism of late years may be due to some alteration in type of the disease I am not prepared to dispute. It may be so, but how can we prove it, and to what are we to refer such an alteration? To better living, better clothing, less wet weather, better draining of our lands, and the more hygienic housing of our population? This may be the case, but I see no evidence of it. But as a hospital physician I avow that we admit no fewer cases of acute rheumatism than formerly; nor comparing the cases I see to-day with those I saw twenty years ago can I perceive any difference in the severity of the general symptoms, or in the degree or kind of its ordinary complication. Still I certainly fail to witness so many autopsies upon cases of rheumatism, and have fewer butter-pat pericardial effusions and solidified lungs, with lymph-coated surfaces, to show my clinical clerks. The cases complicated by pericarditis are less noisy, less restless, less wild in their delirium, often scarcely delirious at all throughout their course. To what shall we attribute this? Is it to salicin, to the salicylates, or to a generally more rational treatment of the disease? I believe it is that we are biased by less theory in our conduct of each individual case, that we do not aim at neutralizing some possible lactic acid, destroying some ferment, or even ousting some poison. We neither purge, nor sweat, nor diuretize, nor nourish our patients so much, nor use an exclusive milk, or alcohol, or broth dietary. We seek, at least I can speak for myself, to ease pain by local sedative applications, and rest over-strained nerves by opiates. We wait till stomach catarrh subsides, and then give peptonized or part-digested meats. For three or four days together, we have learnt, patients can live very well on toast-and-water, and if their tongues are very thickly furred will seldom take much else than warm tea or clear meat soups. A little weak brandy-and-water is often a much more suitable nutriment than a pint of milk, although this is thought and believed to be the simplest, the most entire, and the most suitable of aliments, *Pace* my total abstainer; alcohol is physic. In the treatment of acute rheumatism this gastric catarrh is no unimportant affair; and I believe that the real use of salicylate of soda lies in the good effect

it appears to exercise upon the stomach. The tongue cleans rapidly under the repeated doses of the remedy. There is another remedy which seems to be adapted to the later stages of the malady, to the relapsing cases—the cases, too, which perspire very profusely—this is salicin, which some of you have recently seen me prescribe pretty largely. I give ten grains with one grain of the iodide of potassium and ten drops of the tincture of iodide to an adult every four hours. And this remedy doubtless exercises what virtue it possesses upon the gastro-intestinal functions, for the appetite and digestion improve under its use.

Medical Societies.

MEDICAL SOCIETY OF LONDON.

Case of Intra-thoracic Aneurism.—Treatment of Pleural Effusion.

A MEETING of this Society was held on Nov. 20th, 1882, Mr. F. Mason, President, in the chair.

Dr. Haward showed a man suffering from Intra-thoracic Aneurism. The case was that of a carpenter, thirty-eight years of age, who had suffered from what was taken to be left pleurisy in February, 1882, and had been unable to work since. In June last he began to have throbbing in the chest, and came into the hospital six weeks ago. The cardiac sounds were normal at the apex; but in the second left interspace, half an inch outside the sternum, there was a rough blowing bruit blending with the first sound. There was no bulging or thrill, but a faintly visible impulse. "Each expiration is broken by a series of audible puffs, like the distant snorting of a goods engine. These correspond to the cardiac contractions, and are slightly anterior to the radial pulsation. They are increased in loudness by exertion, and are even felt, as well as heard, by the patient; but after prolonged rest in bed they disappear altogether, returning directly he rises." There was a small bronechocele. In reply to questions put by Drs. Habershon, Hall, and Cavafy, Dr. Haward said that the thyroid enlargement had not increased; he was not aware whether the sound was modified by sleep or repose, and thought the disease to be in an early stage; no laryngoscopic examination was made. The case was referred to a committee consisting of Drs. C. T. Williams, de H. Hall, Thorowgood, and Cavafy, and the author.

Dr. Frederick Hicks drew attention to an improved form of Apparatus for Paracentesis Thoracis. The advantages were:—1st. That it enabled any degree of pressure, high or low, to be used and maintained during the operation. 2nd. That a manometer, for ascertaining the intra-thoracic pressure either at the commencement or during the operation, could be employed easily and without encumbering the apparatus. Two forms of manometer were shown, and their action explained and demonstrated; in one the fluid was mercury, in the other colored water. In the latter the disarrangement of the apparatus by the oscillations of pressure during coughing were divided by a mercurial valve, so constructed as to allow a slow current of air at any pressure to pass freely and affect the water-gauge only, whilst any sudden gust of air acted on the column of mercury, and in doing so closed the tube connecting the trocar with the manometer. The construction of this apparatus was explained, and model shown. The use of the manometer was recommended in all cases of

paracentesis thoracis. The intra-thoracic pressure was not proportionate to the amount of fluid present. In many cases the fluid was under slight or even no pressure, and in some there was actually suction which might amount to half an inch of mercury. Without a knowledge of this condition it was impossible to estimate the force required to withdraw, which if too low rendered the withdrawal less complete, and increased the liability to the sucking-in of air on the patient coughing or taking a deep inspiration, which, if it were too high, blood was easily expressed, especially so in tapping recent effusions. The same apparatus was also adapted for washing out fluid contained in cavities by alternately injecting from one bottle and drawing into another. This was done through the trocar by means of a three-way stopcock, and the opening or closing of the apparatus was unnecessary during the operation. It was important to prevent the accidental introduction of air into the pleura during the various arrangements and manipulations. An instrument was shown for exploring, and if necessary introducing a drainage-tube into cavities in the lungs resulting from phthisis or bronchiectasis, or introducing a drainage-tube into the pleura in cases of empyema when an anæsthetic is not given, but only the skin frozen, and rapidity in operation became a matter of importance.

Dr. Thorowgood made some remarks on the treatment of Intra-pleural Effusions. He commenced by pointing out that the operation of tapping the chest for the evacuation of collections of fluid, though old as the days of Hippocrates, had only of late years taken its position as a recognized and successful mode of dealing with such effusions. Before the days of Laennec the difficulty in diagnosis caused the postponement of such operative measures until the chest bulged or an abscess pointed. Then it was thought justifiable to puncture, but it was common for the enfeebled patient to sink from exhaustion before very long. In his own experience rapid evacuation by the aspirator was almost always followed by speedy reaccumulation, and it was hence his practice to wait three weeks generally in a case of obvious intra-thoracic effusion before aspirating. Brief details of cases were given where pretty copious effusion had become absorbed satisfactorily under small doses of mercury, combined with diuretic mixtures. When aspiration became necessary stress was laid on very gradual evacuation of the fluid under a low suction power. In cases of empyema, as a general rule, the open method of continuous drainage succeeded best, but the details of one case were given where an empyema was treated by two aspirations with a perfectly successful result. The first time pure pus was drawn out, at the second operation, twelve months later, a blood-stained fluid appeared, after which steady and complete recovery followed. As a rule there should not be so long an interval between the tapplings, but if pus appear once in the aspirator, and a week or two later the chest seem to have again filled, no time should be lost in again emptying it, so that the lung may have a chance to expand. A case seen with Mr. Bullock, of Isleworth, proved the expediency of this course. A youth had an empyema on the right side, which was evacuated by aspiration. In eight days' time the pus again collected and was let out by free incision, and a drainage-tube was inserted, the operation being done antiseptically. In two months' time recovery was complete, the lung filled well, and there was no deformity. Washing out the chest was only required when the discharge was offensive, the great point being to secure free drainage. Dr. Thorowgood drew at

tention to right hydrothorax being sometimes caused by cirrhosis of the liver, and the details of a well-marked case were given.—Dr. Green pointed out the different objects with which paracentesis was performed in a case of serous and in one of purulent effusion. In the former it was only needful to remove the intra-thoracic pressure, and for this he preferred Dr. Hicks' method. The cases marked by the greatest amount of effusion were those that were most insidious in onset and least attended by pyrexia. In such cases he did not anticipate much benefit from drugs, but advocated early operation.—Dr. C. T. Williams thought that in very early stages drugs were of service. So far as his own experience went, the cases treated by aspiration did better than the others. The occurrence of pain in the side was an indication for ceasing to withdraw fluid, the remainder being always absorbed. He mentioned a case in which paracentesis was refused, and where treatment by drugs took a year to accomplish the cure. He had not seen much success from division of ribs or cartilage.—Dr. Hall remarked on the importance of a counter-opening in the lowest part of the chest in empyema, to efficiently drain the cavity.—Dr. Symes Thompson thought in sero-purulent cases it was important to empty the pleural sac completely. In such cases Dr. Hicks' apparatus for the introduction of air was useful.—Dr. Hicks said he strongly advocated the use of the least possible amount of suction in treating pleural effusions, the aspirator being used only as a safeguard in case the tube became blocked. The danger of making an opening very low down was that it might get blocked by the diaphragm.—Dr. Thorowgood thought that in serous effusion the use or not of the aspirator was of minor importance.

The Treatment of Syphilis.—The Difficulty of Diagnosing true Syphilis in Females.

A meeting of this Society was held on Nov. 27th, 1882, Mr. F. Mason, President, in the chair.

Dr. Drysdale read a paper on the Treatment of Syphilis. He first alluded to the growing belief in a specific germ in syphilis, and exhibited a specimen sent him by Dr. Ehland, of Stockholm, showing the fungus from gonorrhoeal discharge. The treatment of syphilis was still undetermined. Dr. Fournier advises the use of interrupted courses of mercury for two years and ten months, in daily doses of about one grain and a half of the proto-iodide; Dr. Keyes, of New York, recommends a daily dose of about half a grain of the same salt, given continuously, perhaps for three or four years; whilst in London there was scarcely any regular treatment of the disease by prolonged courses of mercury, and in Edinburgh some practitioners give no mercury at all. Syphilis was introduced into Europe in 1492, and first treated by inunction in 1497. Paracelsus first gave mercury internally in 1570; and until 1812, in this country, there could be little doubt that mercury had poisoned fatally perhaps as many patients as had been killed by syphilis, which until 1836, when Wallace, of Dublin, published in the *THE LANCET* his account of the treatment of tertiary syphilis by iodide of potassium, must have been a terrible disease. It was now known that syphilis varied very much in intensity, a certain number of cases getting well without any local measures. He himself had treated syphilis with iodide of potassium only; but Fournier and Hutchinson were so positive as to the power of mercury to prevent tertiary symptoms that he had begun to regard mercury as a possible germicide, and for some years past had given it continuously for months to all patients

with well-marked sore or with secondary symptoms. He gives one-sixth of a grain of the proto-iodide or one grain of mercury with chalk, and since he has used this treatment he has not met with any salivation, whilst at the same time, so far as he knew, the patients have had a complete immunity from tertiary symptoms. When iritis supervened or severe rheumatic pains with headache, he increased the dose and prescribed inunction. He advocated the early commencement of mercurial treatment and its prolonged use on the ground of its antagonism to the syphilitic virus.

Dr. Routh read a paper on the Difficulty of Diagnosing True Syphilis in Women, and the Nature of its Contagion, with the especial view of combating the Contagious Diseases Acts. He particularly dwelt upon the insignificance of the initial lesions in women leading to their being overlooked on examination, and spoke of the extreme virulence of the syphilitic poison. He then remarked that it was proved (1) that a female could contaminate by her secretions alone, quoting several French and English authorities, and that Fournier extended this contagious power to three or four years; (2) or by mediate contagion owing to promiscuous intercourse; (3) by women who had been cured of syphilis so as to be incapable of re-inoculation and yet fertile sources of infection. He maintained that the contagion of syphilis was intensified in virulence wherever brothels were tolerated, as illustrated by reference to reports from France and Brussels; and that the danger of licensed houses was increased by the inadequacy of examinations. He also showed from the English data of the Contagious Diseases Acts that true syphilis was more severe in the protected than in the unprotected districts, the number of constantly sick being greater, and that even Mr. Lawson admitted the chance of a soldier contracting syphilis in the former as compared to the latter is as 36 to 33; and that for the last two years from the Army Reports syphilis had increased in the former 57 per cent. in the latter 45 per cent.—Dr. Drysdale confirmed the statement as to the increase in the prevalence of soft sores in London and Paris of late years; and also that syphilis had increased in Paris, which he attributed to the clandestinity caused by the police regulations.—Dr. F. Simms agreed with Dr. Drysdale's remark, and added that the presence of a soft sore was an unsafe reason for inferring the absence of syphilis. It was hard to diagnose a primary sore with certainty.—Mr. H. Lee suggested that the Society should undertake the preparation of a scientific digest of the evidence respecting the working of the Acts. Before the passing of the Acts syphilis and gonorrhoea were decreasing, but now both are on the increase. He corroborated Dr. Routh on the extreme difficulty of diagnosing primary syphilis in the female, and the same with respect to gonorrhoea. He had produced the characteristic pustule by inoculating the discharge from the healthy vaginal membrane of a syphilitic woman. The army returns were defective in not giving the cases of secondary syphilis or in distinguishing soft and hard chancres. In women the diagnosis was more difficult by the absence of the characteristic symptom found in men—the enlargement of the inguinal glands. As women only were examined under the Acts, the difficulty in diagnosis seemed to cut at the root of the scientific value of the statistics. It was a question whether one-tenth of the money that these Acts cost to execute, spent on sanitary objects in barracks, would not do far more than the execution of the Acts.—Mr. St. George Mivart drew a distinction between the French system, which had broken down from the brutality of the police, and

the English; and Dr. Routh's arguments were mainly drawn from the former. The most common source of infection he believed to be mucous tubercle, and not primary sore.—Mr. Edmund Owen had found that soft sores were apt to become indurated, and to be followed by secondaries, whilst infection not uncommonly was the sequel to a sore which never bore typical induration, and he believed beyond doubt in the unity of syphilitic virus. He protested against Dr. Routh's conclusion that the working of the Contagious Diseases Acts increased vice and propagated disease. The evidence given before the Select Committee had led its members to form the opposite conclusion.—Dr. Drysdale and Dr. Routh briefly replied.

Microscopical Demonstration of Various Forms of Bacteria.

A meeting of the above Society was held on Dec. 4th, 1882, Mr. F. Mason, President in the chair.

Dr. Heneage Gibbs showed a large number of specimens of Bacteria, including bacillus anthracis, bacillus tuberculosis, from cattle and the human subject; the so-called "typhoid bacillus," putrefaction bacilli; bacilli from septicæmia, diphtheria, sheep-pox, purples; bacilli from the Welbeck poisoning case; and the so-called infective micrococci from the spleen of a tubercular patient. A great part of the evening was spent in the examination of these specimens. After speaking in detail about the specimens and the mode of preparation employed in the tubercular cases, Dr. Gibbs drew attention to the two forms of tubercle met with in the human subject, as already defined by Klein, the reticular and non-reticular forms (specimens of bacilli in both were shown). In the former class of cases bacilli were rarely found; in his own observations in one lung out of every ten, and then in the smallest numbers, singly or in groups of three or four in the meshes of the reticulum. In the non-reticular tubercles, on the contrary, bacilli were of almost invariable occurrence in large numbers, and were aggregated into masses especially to be found in the caseous centre. He was inclined to think that the latter form indicated a more acute disease, than the former. Bovine tubercle was always of the reticular form, with large and numerous giant cells, the tubercles being aggregated in large masses, which are caseous in many places. In bovine reticulated tubercle, however, bacilli were abundant; found, not as in the human subject, solely in the reticulum, but partly around the edge of the caseous region, and partly in the interior of the epithelioid and giant cells. He was inclined to think that this bacillus would prove to be of a different kind from the human one. He had found the bacillus in the liver and spleen, but not in the omentum.—On the motion of the President a cordial vote of thanks was given to Dr. Gibbs for his excellent demonstration; and to Messrs. A. & J. Beck for their kind loan of microscopes.—Dr. C. T. Williams remarked on the failure, in other hands, of Koch's and Ehrlich's methods of obtaining bacilli, and the universal success of Dr. Gibbs' mode. Had Dr. Gibbs detected the bacillus in the blood? He himself had not been able to do so. By Dr. Gibbs' method he detected bacilli in the sputa of nearly all cases of advanced phthisis, but not in all. He thought they were most difficult to find in cases undergoing partial recovery.—Dr. R. Crocker thought Ehrlich's process more successful than Dr. Williams represented.—Dr. Heron said that Koch's process was very difficult, and had been lately abandoned by Koch himself in favor of Ehrlich's process of floating the cover-

slip in a solution of fuchsin. Fuchsin is precisely the same thing as magenta, though various specimens of either were slightly different in tint. The cover-slip was washed in nitric acid (one part to two of water), and the specimen then stained with methylene blue. This process, therefore, was practically identical with that of Dr. Gibbs', whom he personally thanked for his labors.—Mr. Jabez Hogg thought the greatest advantage of Dr. Gibbs' method was that low powers might be used in it. The distinction between various specific bacilli was not at present clear, and it was questionable whether these bacilli of tubercle are really characteristic of this affection.—Dr. Green presumed that the Fellows were prepared to assume with M. Koch the essential connection between the bacillus tuberculosis and the tuberculous processes. Was there, he would ask, any relation found between the number of bacilli and the stage of the disease? He had still to hear what the conditions were which enabled the bacillus to produce its effect.—Dr. Gibbs, in reply, said that he had not examined the blood for bacilli. His method of mixing rosaniline with aniline to form a definite compound was totally distinct from Ehrlich's. Fuchsin would not combine with aniline.

An Improved Invalid Carriage.—Transplantation of Skin in the Treatment of a Large Hairy Mole.—Talipes Varus treated by Partial Excision of Tarsus.—Bronchiectasis, treated by Tapping.

At the meeting of the Society held on Dec. 11th, 1882, Mr. F. Mason, President, in the chair, Mr. Richard Davy exhibited an Invalid Carriage he had devised, capable of carrying one, or, at an emergency, six injured persons, in addition to the surgeon and the driver. The carriage was drawn by one horse, and could be shunted on to a steamer or railway-truck; was of large cubical capacity, and admitted plenty of fresh air and light; the door facing a platform for easy ingress or exit. The stretchers are comfortable and strong, and could be easily slung to the roof. Journeys not exceeding twenty miles could be undertaken by road. For the surgeon there is ample space, a floor easily cleaned, and ready means of communication with the driver. A cupboard beneath the driving-box contains surgical requisites and food. Mr. Davy commented on the exorbitant rates and bad accommodation furnished by railway companies, and stated that his carriage had been appreciated by invalids, pointing out the comfort arising from a system that required no change of conveyance in going from one place to another. The carriage was constructed by Mr. Burt, of Swinton-street, W.C.

Mr. W. Pye read notes of a case of a large Hairy Mole on the forehead treated by Transplantation of a Skin-flap from the arm. The patient, who was exhibited, was fifteen months old when admitted into the Victoria Hospital with a very disfiguring hairy mole occupying the right half of the forehead. It was plain that simple dissection or destruction by caustics would involve great risk of deformity to the eyebrow and lid, besides the unsightliness of the resulting scar. It was therefore decided to cover the wound with a flap of skin from the forearm. The flap dissected from the forearm was left attached to the wrist; the mole was completely dissected off, the arm brought up and the flap adjusted to the wound by several sutures. The arm was then fixed in position by strapping and bandaging, and the sides of the wound in the forearm were partly brought together with sutures. Within twenty-four hours the flap had united at all the joints, where it was in contact with the edges of the wound. On the third

day, however, the side of the scalp became tumid, and the eye became irritated by the discharge. The flap was therefore detached from the arm on the fourth day, and after a little of it had sloughed the wound healed rapidly. There is now only a fading circular cicatrix marking the place of the original mole. The surgical interest of the case consisted in (1) the method of treatment employed, (2) the fact that the pedicle was taken from the distal side of the forearm with no ill effect, and (3) that the pedicle was divided as early as the fourth day.—Mr. Rose had lately performed a similar operation on the hand, using a flap of skin from the abdomen. He divided the pedicle by degrees at the end of a fortnight. Mr. Pye was to be congratulated on the flap living after so early a division of the pedicle.—The President remarked that wounds in children united earlier than in adults. It was fortunate that the child could be induced to keep its arm quiet. He had never divided a pedicle at so early a date. He showed two photographs of cases. In the first, a hairy mole, he had used ethylate of sodium without success, and subsequently nitric acid. In a case of artificial nose he had transplanted a large flap of skin from the forearm to the forehead successfully without any pedicle.—Mr. Davy had used for many years a very fine needle with thermo-cautery in removing hairy moles in preference to excision. In young infants, however, extensive wounds of the skin might be made without much ultimate deformity.—Mr. Pye said that he had fixed the arm with strapping and bandages, keeping the child under the influence of opium. He thought the mole could not have been removed by the thermo-cautery without leaving a large scar. The mole was raised and deep. He had no alternative between dividing the pedicle and letting the eye slough.

Mr. Rose read notes of a case of Talipes Varus in a boy aged thirteen, who was successfully operated on by removal of a wedge of bone from the tarsal arch. Casts of the right foot were shown before and after operation, the second cast showing the foot in good position. The patient had been operated on by tenotomy four times at other hospitals without result. The operation was performed antiseptically on April 14th, and the boy left the hospital on June 3rd plantigrade. Mr. Rose brought forward the case as another link in the chain of evidence in favor of this operation, which should, of course, be restricted to cases in which instrumentation and tenotomy had failed, and where, without this last resource, the patient would remain a permanent cripple. The cast of another case was shown, operated on fourteen days ago, the position of the foot and progress of the case being very satisfactory.—The President doubted the necessity of removing so much bone. Did Mr. Davy use Listerism?—Mr. Davy was glad to see this operation making way, and promised to show some patients operated on by this method at a future day. The insertion of the peroneous tendon was as a rule involved. It was of no importance whether the tendon was cut or not. He did not use Listerism. He had but one death in twenty-five cases.—Mr. Rose said his patient walked away within two months of the operation.

Dr. C. T. Williams read notes of a case of Bronchiectasis treated by Tapping. The case was that of a man, aged forty, admitted into Brompton Hospital in April, 1882, with a history of continued cough and expectoration (latterly fetid) of a year's duration following pleurisy. The physical signs pointed to double chronic pneumonia, adhesion of right pleura and numerous bronchiectases of the right lung, the spots of gurgling being seated in the second and third interspaces near the

shoulder, in the fourth and fifth outside the right nipple, and posteriorly near the lower angle of the scapula. Antiseptic measures failing to reduce the fetor, Professor Marshall, at Dr. Williams' request, made a vertical incision from the fourth to the sixth rib, along a line marked out by the latter, and plunged a trocar and director (specially devised by Dr. Hicks) to the depth of four inches in the direction of the root of the lung. Air hissed out of the opening, and a quantity of fetid matter and sloughing debris was forcibly ejected. The opening was enlarged and a drainage-tube inserted. All fetor ceased, the cough moderated, the temperature fell to normal, and the patient took exercise in the garden. Nineteen days later the discharge increased and became thoroughly fetid, the temperature rising to 101.4°; there was some headache. The discharge continued, but became fetid; vomiting, followed by drowsiness and left hemiplegia, ensued, and death by coma took place on July 6th, forty-five days after the operation. An abscess was found in the left cerebral hemisphere; there was chronic pneumonia, an adherent pleura in the left side, and numerous small bronchiectases, as well as some larger ones, in the left lung, the largest, of the size of an orange, having been the one tapped. No tubercular or caseous masses were found. The case illustrated the difficulties of dealing with bronchiectasis, especially of the globular or saccular variety. By loss of their contractility the tubes were converted into mere bags of putrescent matter, which became absorbed and caused pyæmia. The diagnosis was tolerably exact, and, fortunately, the largest bronchiectasis was reached without much difficulty, and the first results of the operation were thoroughly satisfactory. He alluded to the value of a vertical skin incision over interspaces, to allow, if necessary, a second puncture into the adjoining space, and to Dr. Hicks's director attached to the trocar and cannula, which enabled the opening to be readily enlarged for the introduction of the drainage-tube. This was the fourth case of bronchiectasis which Dr. Williams had tapped, but was the only one where death ensued from cerebral abscess; in two others septicæmia of the opposite lung was the cause. One patient was still living after two years' interval, but the chief difficulty lay in the number of operations which were sometimes necessary to establish efficient drainage.—Dr. Symes Thompson said that the difficulty in these cases was that the dilatations were seldom single. In one case Dr. Williams had made as many as six incisions. The irritation of retained secretions could not be successfully overcome by inhalations.—Mr. E. Owen asked whether Listerism was essential to these cases. In a case he had recently operated on for Dr. Broadbent, excellent results had followed without it. Was it worth while keeping germs from the wound while they could enter by the bronchi?—Mr. Hubert Smith thought antisepticism useful when pleural adhesion had not taken place.—Dr. Williams, in reply, said that in such cases something must be done, otherwise the fetor would render a hospital uninhabitable. He had left the surgical treatment of the case in Mr. Marshall's hands. Free drainage was the main point. It was his first case before operating to ascertain that the pleural layers were adherent.

DIPHTHERIA.—At Port Washington, Long Island, U. S., ten persons in one family are said to have been suffering from diphtheria, which is supposed to have been contracted by drinking from a tin dipper which had been used by a boy in a neighboring family who had the disease.

PATHOLOGICAL SOCIETY OF LONDON.

Casts made with New Material.—Diffuse Polypi of Colon.—Large Polypus of Rectum.—Polypus of Small Intestine.—Abscesses in Liver of Kangaroo.—Abscess and Pyæmia in a Python.—Changes in the Nerves in Infantile Paralysis.—Changes in Nerves after Amputation.—Hypertrophy and Softening of Bones in a Child.—Addison's Disease without Bronzing.—Bone and Brain Disease in Syphilis.—Micro-organisms in Pyæmia.

THE ordinary meeting of this Society was held on December 19th, 1882, the President, Dr. Wilks, being in the chair. Dr. Goodhart's specimens of extraordinary thickening and softening of the cranial bones were referred to the Rickets Committee. Dr. Lees showed a living case of erythema papulatum in a boy aged three years.

Mr. Bowlby showed some excellent casts of Limbs and Skin Eruptions made from a new material, the composition of which was described in the *British Medical Journal* a short time ago. The most important question was as to the durability of the specimens; some of those exhibited had been made nearly a year, but possibly it might be found advantageous to add some preservative like arsenic. The coloring of the skin eruption was done after the cast was made. His second specimen was a Colon of a man, aged sixty years, with diffuse Polypoid growths. There was no other disease of the alimentary canal found, and there were no symptoms during life. The growths commenced immediately beyond the ileo-cæcal valve and extended as far as half way down the descending colon. Some were sessile and some pedunculated. They consisted mostly of soft mucous membrane, and had no relation to any particular part of the circumference of the bowel.—Mr. Bowlby also showed a very large Fibro-cellular Polypus of the Rectum. The patient was a girl, aged twenty-four, who previous to the discovery of the tumour had felt no discomfort beyond occasional constipation. While straining at stool she felt something come down which she was unable to return, and Mr. Everley Taylor, of Scarborough, having been called in, found a large mass, the size of a fetal head, protruding from the anus. The tumour was removed under chloroform and was found to be very succulent, much fluid escaping when it was cut into, and its weight was thirty-one ounces. Its attachment was to the anterior wall, and it consisted of very loose fibrillar tissue containing a considerable quantity of fluid—i. e., a soft fibroma. The mucous membrane over it was normal. It is now ten months since its removal, and there has been no recurrence. Its large size, and the absence of symptoms, were the most noteworthy features. His fourth specimen was a Polypus of the small Intestine. A female, aged thirteen months, under the care of Mr. Morratt Baker, was taken ill, with symptoms of intussusception, on April 28th. She was admitted to St. Bartholomew's Hospital on May 10th, when the vermiform appendix was found hanging loose from the anus, and on the 13th a large portion of the gut came away. The child immediately began to recover, and was discharged from the Hospital on the 19th with the motions fairly healthy. On June 1st it was readmitted with wasting and congenital syphilitic rash, and it died from marasmus on July 2nd, without any symptoms of intestinal obstruction. Post-mortem, there was evidence of old peritonitis and adhesions of the coils together, and also to the enlarged mesenteric glands. The upper part of the small intestines was healthy.

There was a polypus about eight inches from the anus, with ulceration of the gut above it. There was no colon, but there were signs of the restitution of the continuity of the canal, three inches and a half from the anus. There was very little constriction; but the gut above was dilated. The peritoneum was scarred and puckered. The polypus was doubtless the cause of the intussusception; but it was unusual for the polypus not to come away.—Dr. Coupland alluded to a case something like Mr. Bowlby's that was under his care two years ago, the details of which were published in the *Clinical Society's Transactions*. The patient was twenty years of age, and abdominal section was performed for irreducible intussusception. The polypus was in the small intestine, and produced the intussusception which came through the ileo-cæcal valve. Alluding to Mr. Bowlby's case of multiple polypi, he said there was a specimen somewhat similar in the Middlesex Hospital Museum.—Mr. Cripps remarked on the large size of the rectal polypus; and with regard to the disseminated polypi, said there were only four cases recorded in the *Transactions* of the several Societies and in the museums. The specimen that Dr. Coupland had alluded to was taken from a man whose symptoms dated from an attack of cholera, and he died six months afterwards. There was another specimen in Guy's Hospital Museum where there were about twenty polypi in the last twenty inches of the colon with long, slender pedicles. He had shown a specimen himself last year. There were two kinds of polypi: (1) Those formerly called villous tumours, which consisted of hypertrophy of the mucous membrane, with new epithelial layers over the retiform tissue; (2) deposit in the submucous tissue of a mass of cells, the pedicle being formed subsequently, analogous to the fibrous molluscum of the skin. He saw Mr. Bowlby's case of intussusception during life, and asked how it was that the small intestine, which must have come down through the ileo-cæcal valve, did not also slough.—Dr. Wilks thought from his experience that polypi generally occurred in little boys.—Mr. Morris was surprised to hear polypi spoken of as rare. He recollected seeing several cases shown in one evening at this Society, all from young children. He once operated on a woman who had polypus, fistula, and hemorrhoids, and related a case of a man who complained of tenesmus and spasm of the sphincter, and on examination six or eight polypi could be felt in the rectum.—Dr. Goodhart said that he had met with three kinds of polypi in the museum of the College of Surgeons:—1. Like the large specimen shown to-night, which was like Mr. Curling's case. 2. The polypi of young children, which consist of mucous membrane, and are papillomata. 3. Villous, like Mr. Henry Smith's case, where twenty or thirty were removed by the finger, but recurred. With regard to the intussusception, he thought that the colon usually sloughs, and leaves the small intestine behind.—Mr. Bowlby, in his reply, said that disseminated polypi were usually mucous. The interest of his case lay in the fact that his had a fibrous consistence. He thought that the ileo-cæcal valve in the intussusception case, as well as a part of the small intestine, had sloughed away.

Mr. J. B. Sutton showed, first, the Liver of a Kangaroo, with about 200 small abscesses, some projecting above the surface and some deeply imbedded. All of them had caseous walls. One had burst into the peritoneum and killed the animal. He had often seen similar abscesses in birds. Secondly, he related the case of a Large Abscess occurring in the Abdominal Wall of a Python, seven feet long and five inches in circumference, which died four days after admission into the Zoological

Gardens. The cavity of the abscess was lined with layers of fibrin. There were five ounces of bloody serum in the pericardium. The liver was filled with abscesses, from the size of a pea to that of a nut; some of them had only fibrin in them, others pus. In all reptiles there was a communication between the portal vein and the intercostals, and this was freer in the python than in other reptiles through an extra communication. The abscess was situated in the anastomotic area, and led to the hepatic abscesses and the pericarditis.—In reply to the President's question as to the cause of the abscess, Mr. Sutton said that abscesses were common in snakes, possibly from wounds of the intestines produced by the bones which they swallowed.

Sir Joseph Fayrer, in reply to Dr. Wilks, said he was only familiar with multiple abscesses of the liver in the human subject, and he thought that at first they were limited necroses, and then abscesses.

Dr. Walter Edmunds showed microscopical specimens of Nerves from three cases of Infantile Paralysis. The specimens were from three cases in which the leg had been amputated late in the disease as an encumbrance. The sections were from the internal popliteal nerve. They showed considerable increase of the endoneurium in the nerve-bundles and atrophy of many of the nerve fibres. The endothelium in the vessels in the nerve was proliferated.—Dr. Buzzard thought that if the disease be really inflammatory it would probably affect the vessels in the connective tissue first, and where the inflammatory change was the greatest the nerve tubules would be most pressed upon, and therefore atrophied.—Mr. Bowlby thought Dr. Edmunds' view was the correct one, as the separation of the fibres from the nutritive nerve cell would lead to atrophy. He thought the patches of connective tissue were in the site of former motor nerve fibres.

Dr. Hale White and Dr. Edmunds showed microscopic specimens of Neuromata after Amputation, which were, he said, rare in the Society's Transaction, though not really rare tumours. The specimens showed that the first change in the coiled bundles of nerve fibres at the end of the amputated nerve was an ingrowth of delicate connective tissue from the perineurium; this ended in the sclerosis of the bundles, and in its turn the sclerosed tissue underwent fatty degeneration. The reason why the nerve fibres underwent fatty degeneration was that in man the other tissues of the limb not regenerating themselves, there was no need of either sensory or motor nerves. It was pointed out that in the nerve of the amputated limb certain fibres underwent degeneration, which were probably those coming from the parts which had been renewed, whilst the fibres which had not undergone degeneration were derived from the remaining parts of the limb. In a case of amputation of the thigh, the change in the cells of the tractus intermedio-lateralis had not extended as high as the lower dorsal cord. Sections of the median nerve just below a spot where it had been cut through previously showed complete degeneration of the nerve owing to all its fibres being functionally useless. A specimen was also shown of a round-celled sarcoma at the end of an amputated nerve.—Dr. Wilks asked if there was new growth as well as atrophy.—Dr. Hoggan thought that the only satisfactory method was to begin *de novo* the study of nerve pathology by the investigation of the changes in the individual nerve fibres by the improved methods of staining by osmic acid and gold.—Dr. White, in reply, said that his specimens were taken when the changes were too far advanced to show the new nerve fibres, and he

had only quoted from the authorities as to their existence.

Dr. Goodhart showed the Calvaria and specimens of the other bones of an infant, aged fifteen months, who was in the hospital only three days, and died of atelectasis. The mother contracted gonorrhoea from her husband and the child had consequent ophthalmia, but there was no other evidence pointing to syphilis. There are two other children, one with rickets. The patient was suckled for three weeks, and then brought up on milk and water and beef-tea. The child thrived well the first year, but always perspired profusely, had thrush badly, and occasionally spots on the nates, the abdomen was always large. During the last three months the spine had been curved and she cried when moved. A month ago the legs became swollen, then the arms, and then the head. There was well-marked cranio-tabes, the ribs were beaded and the thorax flattened laterally. Node-like lumps could be felt over the inner surface of each tibia and radius, and the lower epiphyses of the radii were enlarged. The spleen was notably enlarged. Post mortem the changes in the bones were the most noteworthy, the bones of the skull being enormously thickened, and also all the long bones and the spine. To summarize the changes:—1. The bones were soft like sponge, and all of them except the petrous part of the temporal bone could be cut with a knife like a raw potato, and one tibia was broken. 2. There was great hypertrophy, mainly, but not exclusively, upon the periosteal pattern. 3. There was marked rickets. The question was whether it was all from rickets or due to congenital syphilis. Parrot has described a similar condition of spongiform osteophytes, but less marked than in this case, which he ascribes to congenital syphilis. Dr. Goodhart thought there was almost too much periosteal growth for rickets, and perhaps the safer plan was to consider it the outcome of both diseases. The infiltrating growth, which even obliterated the medullary canal, seemed to bring it in some relation to osteitis deformans, and some thought osteitis deformans was allied to tumours; and it might be suggested that these changes were more of the nature of a bone tumour.

Dr. Norman Moore thought that the bodies of the vertebrae did not present the changes seen in rickets, and that in the skull the thickening was not increased at the sutures; in both these points it was not like rickets.—Mr. Kesteven asked if there had been any microscopical examinations made.—Dr. Goodhart replied that he had only made an imperfect microscopic examination, and found porous bone. He then related a case of Addison's Disease without bronzing, and showed the abdominal sympathetic nerves which had been carefully dissected out by Mr. Pearson, of the College of Surgeons. The patient was a medical man who had felt ill for a short time and took a sea voyage to recruit himself, obstinate sickness set in, which was ascribed to the effects of the sea, and he landed in a very exhausted state; a few days later he got out of bed and fatal syncope ensued. There was no alteration in the color of the skin. At the autopsy Dr. Goodhart found suprarenal change, and the abdominal sympathetic affected in such a way as to show that there was undoubted Addison's disease. He thought that the case supported the view that if the disease was rapid in its course bronzing might not occur.

Mr. Victor Horsley exhibited specimens of Bone and Brain Disease in Syphilis. The organs shown possess no special interest beyond the fact that successful treatment lessens the opportunities of studying syphilitic lesions. In this case the patient was admitted into University College Hospital under Mr. Hill, from the Lock Hospital,

Soho in a very weak state, and suffering from pyæmic abscesses. What history could be obtained showed his condition to be pyæmic, following on necrosis of the facial and cranial bones. The specimens show, first, the points of necrosis on the frontal and malar bones, together with the spongy bones of the nose, of which the inferior turbinate was found post mortem to be a mere sequestrum, and kept in the nasal fossa by tenacious muco-pus. The whole mucous membrane of the pharynx is hyperæmic, and shows a few cicatrices of previous ulceration. The seats of active mischief were excessively foul, the smell of the discharge not being controlled by antiseptics. The frontal bone shows very well the cicatrices of former ulceration and destruction of the outer table. The lungs on both sides showed some cirrhosis of the apices and broncho-pneumonia; the liver, fatty and cirrhotic, presented a depressed scar on its surface penetrating a quarter of an inch into the substance of the organ. Both spleen and kidneys were cirrhotic, while the former was greatly enlarged, being seven inches long by four inches and a half by two inches. The other abdominal organs showed no particular lesion. On removing the brain there was found an excess of cerebro-spinal fluid, while the arachnoid and pia mater at the base were opaque, and in places matted together by exudation. This did not seem to have caused any paralysis of any cranial nerve. There is asymmetry of the cerebellum, the lateral lobe of the left side being deficient on its under surface at the anterior border, the flocculus being scarcely represented. This does not seem to be the result of disease. There were eleven abscesses in the connective tissue of the limbs and trunk.

Mr. Horsley also showed the Micro-organisms of Pyæmia. There were also shown two specimens of Micrococci, found in the abscess fluid of the case of syphilis and pyæmia first referred to, and also from a case of excision of the tongue for epithelioma. The form of pyæmia in both cases was alike—viz., that in which there is a formation of peripheral, not visceral abscesses—i.e., an infective process not dependent on embolism. As has always been found, the organisms are micrococci, and while always occurring in the abscess cavities, they were not found in the blood. With the fact in view of their invariable occurrence in acute abscess (described by Ogston and confirmed by Mr. Horsley), of course no causative importance was attached to their presence.

Card specimens of Urinary Calculi, chiefly composed of carbonate of lime, from the horse, ass, and dog, were shown by Mr. Shattock; and Cancer of Omentum by Dr. Bedford Fenwick.

CLINICAL SOCIETY OF LONDON.

Cases of Intussusception treated by Abdominal Section.

THE ordinary meeting of this Society was held on Dec. 8th, 1882, J. Lister, Esq., F.R.S., President, in the chair. The evening was occupied by an interesting debate upon the subject of abdominal section for intussusception, introduced by Mr. Godlee in a paper on three cases in which that procedure was followed, one case being successful. The other papers on the agenda had in consequence to be postponed, but Dr. Coxwell exhibited his case of a child with symptoms resembling those of myxœdema. Dr. T. H. Green exhibited a well-marked case of pseudo-hypertrophic paralysis, the patient being a man twenty-four years of age, and the symptoms of the disease only having appeared one year previously.

Mr. Godlee read a paper on three cases of Intussusception in infants treated by Abdominal Section.—Case 1, an infant of nine months, was admitted into University College Hospital with well-marked symptoms of Intussusception, from which it had been suffering for four days. The bowel protruded at the anus. The child was very ill and weak, and it was doubted whether it was justifiable to perform any operation. It was not thought wise to spend much time on attempts at inflation, and accordingly abdominal section was performed without much delay. Antiseptic precautions were adopted throughout, the child being as far as possible protected from the chilling influence of the spray by using as small a volume as possible, and wrapping up the greater part of the trunk and legs in cotton-wool. No great difficulty was experienced in finding the point of involution, nor in reducing the intussuscepted part. The wound was secured as in an ovariectomy, and a dressing of iodoform wool was applied and secured by a flannel roller. The temperature rose the day after the operation to 105°, but soon fell to about 100°. It was necessary to give small quantities of brandy after the operation, and for some few days minim doses of laudanum were given to check restlessness and a slight diarrhoea which ensued. A little suppuration occurred along the course of the sutures, but the wound healed well, and by the eleventh day it had completely closed, the child being apparently in perfect health. Case 2 was a somewhat younger child, who had been seized with milder pain two days previously. The symptoms of intussusception were clear, and a sausage-shaped tumour was felt to the right of the umbilicus, easily movable, especially from above downwards. In the intervals between the spasms the child was apparently free from pain. Under the influence of chloroform the tumour could be easily felt, and it was thought that it diminished under manipulation, but as a considerable mass remained, abdominal section was performed as in the previous case, and reduction was effected by grasping the end of the ileum and drawing it towards the wound. Next morning the child seemed pretty well, but peritonitis set in rapidly and death occurred the following night. The spray used in this case was remarkably small. At the autopsy the last two inches of the ileum and the first two of the cæcum were found much congested and thickened, and some slight ulceration had occurred in the ileum; the rest of the intestines were almost empty. There were marked appearances of peritonitis.—Case 3. A child, fourteen weeks old, was admitted into the North-Eastern Hospital for Children with symptoms of intussusception that had lasted several days. The child was very ill and the abdomen much distended and tender. The bowel protruded at the anus. Abdominal section was performed. It was very difficult to find the point of involution, which was seated deeply in the splenic region, and correspondingly difficult to effect the reduction. After about four inches had been drawn out the cæcum and vermiform appendix appeared, and, thinking that the reduction was complete, Mr. Godlee drew the cæcum towards the iliac fossa and closed the wound in the abdominal wall. The child never rallied, but died eight hours after the operation. At the autopsy it was found that seven inches of large intestine still remained unreduced. It was clear that the involution had commenced, not, as is usually the case, at the ileo-cæcal valve, but at some point in the course of the transverse, or perhaps the ascending colon. Some sloughing had already occurred in the cæcum. Mr. Godlee pointed out how easily such a mistake as that which he made in the last case may occur, and the

manner in which it may be avoided. He did not feel discouraged by the result of the last two cases, but whenever the gut protrudes at the anus he would at once proceed to the operation, or at all events would not waste much time in attempting inflation. On the other hand, in cases such as the second recorded he would give inflation and injection a good trial, since these are the cases most likely to be cured by this proceeding, and they are better able to bear the exhausting results which it causes. Moreover it is clear that the danger of peritonitis is a real one, even if the operation be carried out antiseptically.

Mr. G. Brown read notes of a Case of Intussusception in a boy fourteen years of age, who was suddenly seized with pain in the abdomen. The bowels having acted in the morning, Mr. Brown saw him often throughout the day. There was constant pain, tenesmus, and mæna; and Mr. Brown diagnosed the case to be intussusception. Opium was given without relief. Next day the intussuscepted gut could be felt per rectum. A consultation was held with Dr. Cholmeley, who advised insufflation, which was ineffectually tried, and the next day Mr. Brown performed abdominal section. The operation was difficult, and in spite of considerable traction the invagination could not be reduced. An attempt was then made to perform colotomy, but the colon was found to be filled with adherent small intestine. Death took place six hours after the operation. Mr. Brown remarked upon the rapid evolution and severity of the symptoms in the case. Another time he would not, as in this case, make the incision over the tumour, but in the middle line of the belly.—Mr. Bryant congratulated Mr. Godlee on his courage in acting on his opinion as soon as he could do so. Although only one of the cases was successful, yet each of these cases suggested the value of early operation; for, as regards the two which had failed, valuable time had been lost, and in such young subjects the gravity of delay was great. In all these Mr. Godlee was able to withdraw the intussuscepted portion from the colon, and it had been one of the main objections to the operation that this could not always be done, because whether the bowel is adherent or not depends much on the activity of inflammation. Mr. Bryant said they should bear in mind the analogy between hernia and intussusception. In the early stages of hernia the value of taxis is great, but in later stages it is unjustifiable. So in intussusception: if seen early, temporizing measures, such as inflation, may succeed; but the longer such interference is postponed the chances of success are lessened, and operation becomes necessary to save life. And this must be the course pursued in spite of a few cases being spontaneously cured by sloughing of the intussuscepted gut; just as in hernia, sometimes, when an operation has been refused, spontaneous reduction takes place by a turn in bed or under the influence of opium. He believed if this principle were more often followed more successes would be recorded. He was glad to hear of the facility with which Mr. Godlee effected the reduction by withdrawing the bowel without requiring any process of kneading. His failure in the third case was quite excusable, for the fact of the appearance of the appendix cæci would generally imply that the intussusception had been fully reduced.—Mr. Howard Marsh also congratulated Mr. Godlee on the success of his first case, a success which taught two lessons—viz., the tolerance of infants for such an operation, and the value of mechanical treatment early applied. We were learning by degrees that children bore abdominal section well. Mr. Bryant had pointed out that the difficulties attending operations for intussusception

were purely mechanical, and had rightly compared the condition to that of hernia. Opponents of the operation might argue that it showed very few successes, the fact being that the cases were few in which operation could be expected to succeed. Mr. Brown's case showed in how short a time inflammatory adhesion could occur so as to prevent reduction; but in Mr. Godlee's cases the strangulation did not seem to be complete. For, although in each case blood was passed per rectum, the very fact of hæmorrhage occurring showed, as Dr. Hilton Fagge had pointed out, that the circulation was still going on in the partially strangulated bowel. The period at which strangulation comes on is very variable. It is not the time that the intussusception has lasted, but the period during which symptoms of strangulation have been present that is of importance. Thus he had met with a case of a child who had had intussusception for two weeks, but strangulation for only twelve hours. In Mr. Godlee's two fatal cases the operation had been delayed too long, and seeing the good results of abdominal operations he joined with Mr. Bryant in urging early interference, so that, if inflation do not succeed, the operation should be done at once. The severity of an operation is no good ground for its exclusion, if it be the only means likely to succeed. Intussusception is extremely fatal, for, setting aside a few cases of spontaneous cure, almost all die, and therefore he urged surgeons to be on the alert in such cases. Mr. Marsh concluded by advocating the procedure of reduction employed by Mr. Hutchinson as preferable to simple traction.—Dr. F. Taylor agreed with Mr. Marsh on the minor importance of the duration of the intussusception itself as an indication for interference; for during the past year he had had under his care three cases, in two of which recovery took place after inflation. In these cases symptoms had been present for from three to five days. The symptoms of strangulation, however, were not severe, there being very little distension of the abdomen, the patients suffering from time to time from twinging pains. In the two successful cases the invagination yielded to insufflation under chloroform; the children were five and eight years of age respectively. The other case was a younger child, who was in a more collapsed state; inflation reduced the size of the tumour considerably, and it passed from the left side of the abdomen to the right. Opium was given, but in a few hours the tumour returned to its original size and position. Mr. Golding Bird saw the case and again performed inflation, with the same result as before, but collapse ensued. After death examination showed an incomplete reduction, which was completely effected by injecting water into the bowel, but not without causing a rent in the peritoneal coat.—Dr. Mahomed mentioned a case of chronic intussusception lasting nine months, the true nature of which was not clear, notwithstanding the sloughing and passage of a portion of intestine. It occurred to him in that case whether it would not be justifiable to cut down on the bowel and remove it. He therefore suggested that excision of the intussuscepted bowel might be of value in cases which could not be reduced by other means.

Mr. Howse said that the results of abdominal section for intussusception were not very encouraging. Since the case recorded by himself and Dr. Fagge, in the *Med. Chir. Trans.*, he had had four cases, in two of which the intussusception had protruded from the anus. In two of the cases inflation was tried, but owing to their severity operation had to be performed. On each of the four cases he failed to reduce the intussusception. In two he excised the ileo-cæcal valve,

which remained unreduced. But the excision of a piece of intestine with the abdomen laid open was not easy, there being great risk of tearing the softened gut; and he suggested the use of a thin elastic sheeting to shut off the rest of the cavity whilst excising. Another difficulty he met with was in bringing the divided ends of the bowel together, it being very difficult to draw them sufficiently out. It might be well in cases where the intestine protrudes through the anus to adopt another measure, similar to that followed by an Italian surgeon, who, mistaking the condition for one of simple prolapse, drew down the tumour and cut it bodily away; the case did well. Some such procedure as this might succeed, for it would be comparatively easy to cut off the intestinal mass, and yet the peritoneal cavity would be shut off by the adhesions in the intussusception.—Dr. Mahomed added that he should have referred to Mr. Bryant's successful cases of excision of portions of diseased intestine.—Dr. Andrew Clark commended Mr. Godlee for his modest record, and wished to ask whether the effects of such operations on young children had been noted, especially as regards variations in the temperature. If observations on temperature were made during such operations, we might the better understand the various factors engaged in the production of temperature.—Mr. Haward said that no doubt it was very desirable to make the distinction, if possible, between those cases in which the bowel is merely invaginated and those in which it is strangulated. The acuteness of the symptoms was some guide, but it cannot be altogether depended on. There was lately under the care of Dr. Cavafy and himself a child, seventeen months old, whose attack had commenced with vomiting five days before; the bowels were twice opened after the first symptoms, and blood had been passed for two days. On admission the invaginated bowel could be felt per rectum. Ether was given, and injection with inversion failing to effect reduction, the abdomen was opened. Although acute symptoms had been present for five days there was no difficulty in withdrawing the invagination (consisting of ileo-caecal valve and ileum) by slight traction and support from above. The main difficulties now arose. The bowels, being greatly distended with gas, could not be prevented protruding through the abdominal wound. Inversion and gentle manipulation failed to replace them; nor did simple punctures to let out the gas suffice. Finally, the distended coils had to be tapped with a trocar, liberating gas and fluid faeces; before the intestines could be got back. This same difficulty has occurred to others in abdominal section for intestinal obstruction. The child died a few hours after the operation, with commencing peritonitis, which Mr. Haward thought was due to the above protracted difficulty.—Mr. Beck had done this operation six years ago, in a child under one year old, who survived it for thirty-six hours. There was some difficulty in reducing the intestine, which he had to draw out on to the abdominal wall; and he tried to reduce it by both pushing and pulling on the intussusception. During these measures fissures appeared on the surface of the vulvulus, and the child ceased to breathe, but was restored by artificial respiration.—Mr. Pepper remembered the case referred to by Mr. Beck, which raised in his mind doubts as to the propriety of such operations. Since then he had seen one operated on by Mr. Pye, in which the peritoneal coats also split. He pointed out that Mr. Pollock, writing in "Holmes' System of Surgery," says that a very considerable number got well spontaneously, and, if so, it became a question whether it is wise to operate at all.—Dr. Buzzard pointed out that a case

of intussusception was not to be placed in the same category as ovarian disease, where there is no natural attempt at recovery; for in intussusception from the time inflammation (and therefore obstruction) sets in the natural process towards recovery is commenced, ulceration ultimately succeeding in cutting off the intussuscepted part. In every case there is this natural tendency to recovery, but in the majority the patient dies in the process. At the same time he did not wish to discourage the operation, which was often the only chance.—Dr. Glover asked whether belladonna might not do good, and related the case of a child who had obstruction for ten days (not, however, due to intussusception), in which no relief had been obtained under opium and enemata, and abdominal section was on the point of being performed, when belladonna was given—the extract in quarter of a grain dose, every four hours; and after the fifth dose the bowels were freely relieved.

The President said that the Society was to be congratulated upon the valuable discussion and the paper that had given rise to it. Mr. Howse's suggestion, although startling in its novelty, deserved careful consideration, for it was an imitation of the natural process of cure referred to by Dr. Buzzard. The peritonitis in Mr. Godlee's second case was, he felt no doubt, due to the state of the bowel, just as in peritonitis following strangulated hernia, and he did not think it attributable to the spray. In abdominal surgery it would seem that antiseptic precautions are less important than in surgery generally; but it must be remembered that those who say they operate without such precautions do really follow the practice, in scrupulously observing cleanliness in boiling or steeping sponges and instruments, etc., although they do not use the spray. Mr. Godlee took antiseptic precautions, but it was very unlikely that the spray was the cause of the peritonitis, and nothing more likely than that the condition of the bowel determined it.—Mr. Godlee, in reply, said that no doubt in that case of peritonitis the strangulation had lasted longer than in the others. He believed there were very few cases on record where the bowel had separated by sloughing under the age of one year, and inflation was less likely to be successful in such young children; besides, it produced very great exhaustion. Dr. Taylor's cases were older, and the youngest died. He was encouraged by Mr. Bryant's and Mr. Marsh's remarks, and concurred as to the importance of diagnosing the fact of strangulation. It was difficult to know when strangulation occurs, for bloody mucus was passed without there being strangulation, and gripping pains might even occur without it. The plan he adopted in the reduction was unrolling the ensheathing portion from the ensheathed, using very little traction; but these cases proved exceptionally easy to reduce. The temperature rose rapidly in the second case to 103° or 104° after the operation. There was a difficulty in returning the intestine into the abdomen, especially in the second case. He added that, in 1877, Dr. Sands, of New York, published a table giving seven successful cases of this operation out of twenty-one cases.

OBSTETRICAL SOCIETY OF LONDON.

A MEETING of this Society was held on Wednesday, Dec. 6th, 1882, Dr. Matthews Duncan, President, in the chair.

Deciduous Membrane.—Dr. Cleveland exhibited a fleshy finger-like sac, passed forty-eight hours after labour by a patient who after a former labour

had passed a similar substance, which he had then exhibited to the Society. After careful search he had found no trace of a double uterus.—The President could think of no other origin for such an unbroken decidua than that it came from a uterus bicornis.—Dr. Wynn Williams described a case of double uterus at present under his own care.

Microscopic Sections of Carcinoma Uteri.—Dr. Edis showed microscopic sections illustrating his case of malignant disease of the cervix complicating pregnancy. The amount of stroma was small compared with that of the cells, the appearance thus resembling that of medullary cancer.

Perimetritic Abscess.—Mr. Griffith showed a specimen of perimetritic abscess, situated behind the uterus and left broad ligament, displacing and obstructing the rectum, and opening at three places into the cervix uteri, vagina, and rectum.

The Directions of Uterine Contraction.—Dr. Godson showed a uterus removed by Porro's operation, which demonstrated well the wrinkles on its peritoneal surface caused by the contraction of its muscular fibres underneath.—Dr. Routh had heard the uterine soufflé per vaginam or over the sacrum in cases in which he had failed to hear it by auscultating the abdomen.

Retained Placenta.—Dr. Wynn Williams exhibited a placenta retained for three months after abortion, and removed by him.

Fibroids Removed by Abdominal Section.—Dr. Bantock exhibited five specimens of uterine fibroids, weighing respectively 3 lb., 8 lb., 13½ lb., 3 lb., and 2 lb., removed by abdominal section. One patient died, four recovered. In each case the pedicle was secured by Köberlé's serre-nœud, upon the value of which Dr. Bantock remarked. He thought that whatever might be the future of oophorectomy for the cure of fibroids, it could not compete with hysterectomy in cases such as those exhibited, in each of which there were substantial objections to the former operation.—Dr. Robert Barnes thought fibroids such as Dr. Bantock had shown better dealt with by hysterectomy. At present he inclined to think Battey's operation best suited for hard fibroids in the wall of the uterus, and projecting inwards. Malignant and myxomatous tumours it was better to extirpate. He could speak from clear observation of the remarkable effect of Battey's operation upon fibroids. Within a year after this operation he had found a tumour the size of the fist practically gone.—Mr. Knowsley Thornton did not think hysterectomy should be performed for fibroids until oophorectomy had been tried and failed. He had done the latter operation ten times; all the patients had recovered, all had been benefited, and in all the uterus had diminished in size, in some to a surprising degree. Not merely the ovaries, but the tubes, and the large vessels in the broad ligament, ought to be removed.—Dr. Godson corroborated Mr. Thornton's statement as to one of the cases operated on by him.

Dr. Champneys asked Mr. Thornton in what cases he thought the operation should be done.—Mr. Thornton thought only in cases in which life was threatened.

New Lamp.—Dr. Aveling exhibited a modification of Swan's incandescent carbon lamp, so made that it could be introduced into cavities of the body for operative or endoscopic purposes.

Ruptured Perineum: New Method of Operating.—A paper upon this subject, by Dr. Wynn Williams, was read. In this operation the sides of the rent were first denuded in the usual way; then a flap of elastic tissue about two-thirds of an inch in width, about two lines in thickness, and long enough when on the stretch to reach as high as the denuded surface on the labia, was dissected up

from the floor of the vagina. Sutures were then passed through the denuded surfaces in such a manner as to keep the edges as well as the flat surface of this flap in contact with the raw surface. This being done, the sutures were secured in the usual way. When the rupture involved the sphincter ani, the flap was made, and the sutures passed through it in the same way as in the simpler cases, but the rent in the wall of the rectum was sewn up with sutures made to terminate within the bowel, and the deep sutures secured before those bringing the flap into position were tied.—Dr. Aveling asked what was Dr. Wynn Williams's practice with regard to the action of the bowels after operation.—Dr. Bantock objected to the practice of tying the knees together, and also to the use of vaginal injections, after operation. He had performed Dr. Wynn Williams's operation once, but was not much impressed by it.—Dr. Cleveland thought that rupture of the perineum could often be prevented by restraining the too rapid emergence of the child's head, which could be done by judicious counter-pressure.—Dr. Savage thought the difference was overlooked between mere tegumentary lesions and rupture extending through the perineal body. In Dr. Williams's operation a narrow tongue of tegument was reserved in the course of denudation, and plastered over the crevice left after bringing the raw surfaces together. No additional strength resulted from this, because the tongue was merely tegumentary. Early operations were tegumentary, and failed altogether. The perineal body was the centre of attachment of the perineal muscles, and the mainstay of the floor of the pelvis.—Dr. Routh thought that rupture of the perineum could not always be prevented, and sometimes a slight laceration was not so great an evil as prolongation of the labour. He had in early practice succeeded completely with ordinary sewing-needles and thread. He concurred with Dr. Savage's remarks as to the perineal body, but had seen that the perineum made by Dr. Williams's operation was remarkably strong and effective.—Mr. Knowsley Thornton thought this mode of operating gave remarkably good results; but it was not new, having been described by Mr. Teale, of Leeds, and practiced by many American surgeons.—Dr. Murray had seen the operation now described, and thought it gave a firm perineum. It was not always prudent to retard the progress of the head. Laceration of the perineum might often be prevented by making one or two lateral cuts.

Dr. Campbell Pope said that primary union might often be obtained by applying a broad strip of plaster to hold the nates together.—Dr. Edis said that rupture might often be prevented by straightening the legs while the head was emerging, and also by making a nick on either side of the perineum. Union might be obtained by operation twelve or twenty-four hours afterwards. It was unnecessary, and rather jeopardized healing, to keep the bowels constipated after operation.—Dr. Culver James had, in one case, operated immediately after labour with a rather large common household needle, and obtained union.—The President had seen the results of many methods of operating, and could not say that one was better than another. He had stitched up a perineum two weeks after delivery without denudation or cutting of any kind, and it healed sufficiently.—Dr. Wynn Williams did not confine the bowels after operation. The perineum made without the flap he had described was apt to be too thin. He was not aware that his operation had been described before; it certainly was not alluded to in any work on gynecology.

Pregnancy complicated with Cancer of the Cervix; Cæsarean Section; Recovery.—This paper, by Dr.

Edis, was then read. The patient came to the Middlesex Hospital in November, 1881. She had begun to suffer from pain, hæmorrhage, and discharge eleven months previously. She presented the signs of six months pregnancy, and there was epithelioma involving nearly the whole circumference of the cervix and the greater part of the posterior vaginal wall. Palliative treatment was adopted until February, 1882. Labour pains then came on, and the os dilated to the size of a five-shilling piece. It being judged impossible for delivery *per vias naturales* to take place, Cæsarean section was performed by Mr. Morris. The child was born in a state of suspended animation, but recovered. The mother recovered, and when seen in September the disease had made but little progress.

Two Cases of Labour complicated by Cancer of the Cervix Uteri.—These cases were related in a paper by Dr. Herman. In the first case the diseased tissue was freely cut away with scissors and the actual cautery, and delivery effected with forceps. A vesico-vaginal fistula subsequently was formed, then phlebitis, and the patient died on the 18th day. The fistula occurred at a spot which the cancer had invaded. In the second case masses of diseased tissue were removed with the écraseur, the fingers, and scissors, with only trifling hæmorrhage, and delivery was effected with forceps. The mother recovered well. The author thought that in the management of labour obstructed by cancer, the first alternative to be considered should be whether it was not possible to break down, and tear or cut away (the former preferably) the obstructing diseased masses.—Dr. Bate had had a case of labour with commencing cancer, in which delivery was effected by natural efforts, but the patient died from septicæmia.—Dr. Champneys said that in these cases it was perhaps most important that there should be healthy tissue at the sides of the cervix, for it was there that lacerations most often occurred.—Dr. Galabin inquired as to the method of suture of the uterus adopted in Dr. Edis's case. He had in four cases of cancer delivered *per vias naturales*, in one only was there great difficulty in doing so; but two of the mothers died; in one of the latter the disease was almost entirely removed with the galvanic cautery.—Mr. Jennings thought that rupture of the bladder during parturition was not so rare as might be supposed.—Dr. Fancourt Barnes thought that in these cases Cæsarean section offered a chance of probable recovery to the mother and certain safety to the child. An important point was that in this operation healthy tissues were cut through, while in natural delivery diseased tissues were torn, thus favoring blood-poisoning.—Dr. Edis said that in his case interrupted sutures of silk worm gut were used.

OPHTHALMOLOGICAL SOCIETY OF THE UNITED KINGDOM.

The late Mr. Critchett.—*Hydatid Tumour of Orbit.*—*Panophthalmitis.*—*Large Ivory Exostosis of Orbit.*—*Hard Chancre of Inner Canthus.*—*Central Amblyopia in Diabetes.*—*Optic Neuritis.*—*Tortuosity of Retinal Vessels.*

THE ordinary meeting of this Society was held on Dec. 14th, 1882, Mr. W. Bowman, F.R.S., President, in the chair. He alluded in feeling terms to the sad loss they had sustained in the death of Mr. Critchett, in whom they mourned a warm-hearted, true-hearted colleague, and one whose calm and mature judgment, based on long and

wide experience, would be missed by many in cases of anxiety and difficulty. In him Mr. Bowman had lost an almost life-long friend, and although it would be more fitting to attempt a particular enumeration of his claims on some future occasion, he could not help recalling the fact that Mr. Critchett had presided in the chair at the close of the last session. He concluded by reading the following resolutions, which had been unanimously passed by the Council: 1. "That the Council of the Ophthalmological Society of the United Kingdom desire to record their sense of the great loss sustained by the Society, as well as by the profession at large, in the death of one of their vice-presidents, George Critchett, whose extended reputation at home and abroad rested on the solid foundation of important services rendered to that department of the medical art to which he was chiefly devoted, and whose kindness of heart and excellent judgment were universally recognized and esteemed." 2. "That a copy of the foregoing resolution be forwarded to the family of Mr. Critchett with an expression of the cordial sympathy of the Council on the part of the Society under their bereavement."

Dr. P. H. Mules showed a Hydatid Cyst removed from the Orbit, the size of a pigeon's egg. The patient was a boy aged six years; the growth was difficult to diagnose, and was treated by free incision and drainage tubes. The cyst was discharged on the seventh day. Before this, however, a condition of choked disc supervened which interfered with the perfect recovery of vision; but six months after the removal of the cyst he could read.—Mr. Hutchinson asked if any echinococci were found in the fluid.—Dr. S. Mackenzie pointed out that the laminated membrane of the cyst sufficed for the diagnosis.—The President asked whether the firm adhesion of the cyst prevented its being wholly removed at once, for it was very desirable to avoid inflammation within the orbit.—Mr. Milles mentioned a case lately treated at Moorfields Ophthalmic Hospital where the whole cyst was readily removed, and the wound rapidly healed.—Dr. Mules, in reply, said that the cyst was very firmly adherent, and he did not think it prudent to tear it away.

Dr. Mules also gave particulars of a case of Panophthalmitis. Two or three months before the patient had undergone an operation for glaucoma, which had left a cystoid cicatrix. A panophthalmitis, which he attributed to septic absorption through the faulty cicatrix, destroyed the eye within twenty-four hours of the first symptom of purulent infection.—Mr. Priestley Smith said that Leber had recently pointed out the dangers of such cystoid cicatrices. He had himself lately seen a case where the eye was rapidly destroyed from septic inoculation, due probably to an old wound of the iris.—Mr. Brudenell Carter mentioned the case of an old lady operated upon for chronic glaucoma of both eyes, in whom suppuration occurred three years later in one eye, the pus escaping at the cicatrix. There was no evidence of inoculation.

Dr. H. A. Lediard (Carlisle) read notes of a case of Necrosis and Spontaneous Separation of a large Ivory Exostosis of the left Orbit. He showed the portrait of the patient, and also the exostosis itself. The tumour was stated to have been about the size of a pea at birth, and it was situated between the upper eyelid and the eyebrow. It gradually enlarged, and at the age of nine years, induced destruction and rupture of the globe of the eye. The tumour ceased to enlarge at about twenty-five years of age, and, about two years later, the skin, which had hitherto covered it, suddenly gave way. The patient was admitted into the Carnarvonshire

and Anglesey Infirmary, under the care of Mr. Hughes, in 1870. He was then thirty-three years old, a sailor, and in good health. The tumour seemed to arise from the cavity of the left orbit. It was of stony hardness, irregularly pyramidal in shape, nodulated on the surface, and measured 4.5 by 5 inches; the tumour was then movable, and, whilst under observation, gradually became looser; an offensive discharge issued from the base; finally, about a month later, the whole mass became suddenly detached, without any associated pain or hæmorrhage. The tumour was pediculated, and weighed nine ounces. The neck also was much enlarged, the anterior and lateral portions being of stony hardness, the left side being on this account much larger than the right; the girth of the neck was 17.5 inches, and of this a space of ten inches was of stony hardness. In October, 1882, the patient survived, was in good health, and master of a vessel. The vision of the right eye remained good. Dr. Lediard referred to the other similar cases which he had been able to find recorded. Mr. Hilton reports in Guy's Hospital Reports (1836) a very similar case, where the exostosis, which weighed 14.75 ounces, became spontaneously detached. In a case recorded by Mr. Hutchinson in his "Illustrations of Clinical Surgery," and under his care jointly with Mr. Borlase Child in 1859, the exostosis which was of large size, and appeared to spring from the frontal sinus, also became necrosed. Sir James Paget, in his "Surgical Pathology," mentions another case of large ivory exostosis in the orbit, which projected not only forwards, but also backwards into the skull. Dr. Lediard showed a photograph of the skull in this case, which had been sent to him by Professor Humphry, of Cambridge. Boyer had referred to spontaneous necrosis of ivory exostosis, and had remarked on the fortunate nature of the process.—Mr. Hutchinson said these tumours had slender pedicles, and if dealt with early they might be removed without much risk, necrosis being a late event. In Mr. Borlase Child's case it took an hour to saw through the neck; it should have been broken off at the root. A year later, necrosis having occurred, the tumour readily shelled out, leaving the orbit much dilated.—The President recalled a case where an exostosis as large as a walnut projected from the orbit; it was easily shelled out.—Dr. Fitzgerald referred to a specimen in the Museum of the Royal College of Surgeons at Dublin, much resembling that at Cambridge. In a case under his own care the tumour sprang from the roof of the orbit, but he did not venture to remove it.

Mr. S. Snell (Sheffield) communicated notes of a case of Hard Chancre of the Inner Canthus, which occurred in a nurse-girl, aged twenty-one, who had under her special charge a syphilitic infant of five months. The chancre was noticed some few weeks as a pimple before the girl came under observation on Aug. 15th, 1882. It then involved the caruncle and adjacent conjunctiva as well as the integument of the commissure and the lids. A point of interest and diagnostic value was the presence of well-marked induration of the pre-auricular and submaxillary glands. Other symptoms were a papular, coppery rash and alopecia, ulcerated throat, and later on mucous tubercles of the vulvæ. The chancre healed with hardly appreciable deformity.—Mr. Brudenell Carter had seen two instances of hard chancre on the eyelids in young subjects; the mode of infection could not be traced.—Dr. Fitzgerald had seen a case in Paris in a young girl, and had attributed it to direct inoculation.—Mr. McHardy suggested that inoculation might arise from the popular practice of using the tip of the tongue to remove foreign bodies from

the eyes; or the use of moistened blotting-paper for the like object.—Mr. J. E. Adams thought inoculation generally occurred from the sore mouths of syphilitic children through kissing; and Mr. Vose Solomon mentioned a case directly traceable to kissing.

Four papers on the subject of Central Amblyopia in Diabetes were read. The first was by Mr. Lang. The second was by Mr. J. B. Lawford, who gave an account of a case of Stationary Tobacco-amblyopia in a man subsequently affected by diabetes. The patient was forty-six and had always been a heavy smoker. His sight had begun to fail about seven years ago, and diabetic symptoms supervened about nine months ago; but his sight had not deteriorated, though the diabetes had grown steadily worse. Vision was very defective, and there was a well-marked central scotoma for red. The optic discs were a little pale, but the ophthalmoscope revealed no other morbid state.—Mr. Stanford Morton communicated a case of Double Amblyopia, with well-marked central scotoma for red and green, in a man, aged thirty-four, accustomed to smoke very moderately, and who was suffering from diabetes. The patient was not under care long enough (barely two months) for the result as to sight to be known.—Dr. Edmunds and Mr. Nettleship communicated a paper on the same subject. It contained notes of four cases of central amblyopia without ophthalmoscopic changes, in patients suffering from diabetes. 1. A man aged forty, who had suffered from diabetes for several months. He smoked half an ounce of tobacco a day. Failure of sight had been noticed for one month. Vision in each eye 20-100, letters 14 J. (corrected). Under treatment for diabetes, health improved, but not vision. He would not, however, stop smoking. 2. A man, aged thirty-eight, had had diabetes three or four years. He smoked half an ounce of strong tobacco daily. Failure of sight had been noticed for five months. Vision in each eye 5-200 and 14 J. He died in the country three months later. 3. A male, aged forty-eight, had been the subject of diabetes during twenty-one months. He had smoked, during the last thirty years, three-quarters of an ounce of tobacco a day. He had experienced failure of sight for five weeks. Vision was 20-100 and 8 J. 4. A man, aged fifty-eight, a moderate smoker, complained that his sight had been failing for eighteen months. Vision in each eye 20-200 and 16 J. His urine, on examination, was found to contain sugar. Nine cases were referred to by the authors (including published ones) of failure of sight with central scotoma, in the subjects of diabetes without ophthalmoscopic changes. The authors, however, suggested that the coincidence would prove to be fairly common. Most of the patients were smokers, some of them great smokers; and it was not yet certain whether diabetes alone caused the disease, or only acted as a predisposing cause to tobacco-amblyopia. The analogy of double amblyopia to the symmetrical neuralgia in diabetes, described by Worms and Buzzard, was pointed out.—Dr. S. Mackenzie pointed out that these cases had all come under the care of surgeons rather than physicians. He had seen two cases, one in a woman. Tobacco was an important factor in their production.—Mr. Priestley Smith, speaking of the pathology of central amblyopia apart from constitutional or toxic causes, stated that Samelsson, of Cologne, had suggested that inflammation of the central parts of the nerve at or near the optic foramen, causing the amblyopia, might depend on the distribution of the nutrient bloodvessels of the nerve, the capillaries in the centre of the nerve being more numerous than at the periphery. On this view sudden changes in

the vascularity of the face from exposure to cold, etc., might through the orbito-facial anastomoses lead to congestion and inflammation of the central part of the optic nerve. Mr. Smith referred to a case in point.

Dr. S. West read a sequel to a case of Optic Neuritis reported by Mr. Stanford Morton in the Society's Transactions, vol. i. The patient came under Mr. Morton's care in January, 1881. Vision was then perfect, but both discs were greatly swollen; in the following month she consulted Dr. West for headache and for sudden temporary attacks of blindness. Vision began to fail in June, 1881, in the right eye, amounting to J. 2, and 20-30, and the field of vision was much contracted; headache worse. At the end of July, 1881, vision in the right eye was completely gone and was defective in the left. She was very actively treated with mercury and with iodide of potassium on several occasions, but without any good result. In September, 1881, she was completely blind in both eyes. The swelling of the disc remained; atrophy gradually ensued, so that in August, 1882, the discs were quite white and extremely atrophic. In November, 1882, there was no perception of light; the pupils did not react to light, but freely to movements of the eyeball; the eyes diverged but could fix fairly well. The condition was probably secondary to some tumour of the brain, possibly a tubercular tumour, which had become stationary or retrogressive, but the diagnosis was exceedingly difficult. The case was of interest, owing to the persistence of perfect vision for about five months in the presence of extreme optic neuritis, to the attack of temporary complete blindness, to the rapidity with which the failure of vision became absolute when once it commenced, and to the entire absence of any symptoms beyond the eye changes.

Dr. S. Mackenzie showed a drawing of the Fundus, exhibiting great Tortuosity of the Retinal Vessels, from a patient, aged twenty, who was suffering from severe vesicular emphysema, oedema of the legs, and lividity. The veins in the fundus of both eyes were extremely tortuous, dark, and somewhat dilated. This condition of the veins would, perhaps, have been attributed to the venous obstruction consequent on the emphysema but for the cases recorded by Messrs. Nettleship and Benson, where the condition was noticed in otherwise healthy eyes.—The President had occasionally seen cases, mostly women, of small varicosities in the episcleral region, without impairment of the functions of the eye. In some other cases glaucoma eventually supervened, but he had not operated for fear of hæmorrhage, a fear which iridectomy shows to be unfounded. In some of these cases the retinal vessels also were enlarged.

Dr. Edmunds and Mr. Lawford exhibited Microscopical Sections of the Optic Nerve from a case of Amblyopia in Diabetes. The patient had been a hard smoker, and sight had been failing for about four months. No ophthalmoscopic changes were detected. He died of diabetes. The section showed changes limited to a group of fibres which extended through the length of the nerve—viz., a thickening of the connective tissue with degeneration of the nerve fibres.

Mr. Juler showed again the case of Chronic Membranous Conjunctivitis exhibited at the last meeting. The right eye had recovered under the use of lapis divinus, but the disease had extended in the left.

Mr. J. E. Adams showed a case of Chancre of the Upper Lid, an indolent shallow ulcer, with surrounding thickening on the under surface of the left upper lid near the outer canthus, and a very marked adenopathy on the same side. It was

too early to allow of an absolute diagnosis, since no secondary symptoms had as yet appeared.

Mr. Gunn showed a girl with Peculiar Appearances in the Right Retina below the disc, probably congenital.

Mr. Adams showed a case of peculiar congenital Opacity in the Capsule of the Crystalline Lens.

MEDICAL OFFICERS OF HEALTH SOCIETY.

At a meeting of this Society, held at Adam-street, Adelphi, on November 17th, 1882, the President, Dr. J. W. Tripe, in the chair, a paper was read by Mr. Rogers Field, M.I.C.E., on "Certain less recognized, but highly important, points in the Drainage and Ventilation of Houses," of which the following is an abstract:—Three sanitary principles govern house-drainage. These are: 1. All refuse matter must be completely and rapidly removed from the house. 2. There must never be any passage of air from the drains or waste-pipes into the house. 3. There must be no connection between the drains and the domestic water-supply. These principles, although so simple, are very frequently neglected. The first goes absolutely to the root of sanitation; for were it strictly complied with there would be no leaky drains, no polluted subsoil, and no production of foul gases in the drains from decomposing organic matter. There cannot be a greater mistake than to assume, as is commonly done in investigating drainage, that if water runs away with freedom this is all that is required; numerous cases are on record where the sewage from houses has apparently run away freely for years, but where the greater portion of it has really been leaking out of the drains into the ground under or close to the house. In illustration of this point the author quoted two cases in his own practice: one in which the connection with the sewer was actually found to be blocked with shavings, which had been left in when the house was built three years before; the other that of a school, in which the drainage from the lavatories had leaked through disused drains under the floor of a large portion of the building, and where, although there was a mass of filth in some places seven feet deep, no leakage had been suspected. If the drains are exposed and found clean and jointed with cement, this is not sufficient; the tops of the joints may be good and the bottoms bad. The only safe method is to actually test the drains by plugging them at the lower end and filling them with water; very few house drains indeed stand this test. Even if the drains are outside the house, it is a mistake to assume that it is unimportant whether they are sound; for not only may sewage leak out of faulty joints and percolate under the house, but foul air may be drawn into the house. It is important to realize how small an amount of deposit will create mischief by decomposing and degenerating foul gases, a mere irregularity of the joints even when the drain has a good fall is sufficient to cause this. There is no better test of the condition of the drains than the amount of smell emitted from a ventilating opening, for if drains be properly laid and in thorough working order, practically no smell should exist. Examples were given. Faulty forms of traps and water-closet apparatus were strongly condemned by the author, and diagrams descriptive of good and bad closets were exhibited. The principle that there should never be any passage of air from the drains or waste-pipes into the house was then considered, and the means of isolating the house drains from the public sewer, the necessity of keeping the drains outside the house, their ventilation as well as that of the soil-pipes,

the position of the water-closets, the disconnection of the sanitary fittings inside the house from the drains, were referred to. It was insisted that the danger should be guarded against of trusting too much to those parts of the drainage of a house which are visible as an index of the condition of other and important parts which are concealed, and an instance was mentioned of a house the drainage of which had been recently reconstructed, and where all the sanitary arrangements appeared at first sight to be perfect, but where a subsequent examination of the drains, which were under the house, showed that the joints were in many places defective, and at one point the pipes were not jointed at all, but a space left large enough to put a hand in, though it was stated that special care had been taken to make the drains watertight. Old drains, which had no outlet connected with gullies, were found beneath the passages and rooms; the housemaid nearly died of typhoid fever, and beneath the room she occupied was found an old drain with a large amount of foul deposit. A long list of other defects was described, leading to the conclusion that the drainage instead of being very good was really so radically defective throughout that it was necessary to reconstruct the whole of it. Another instance was given in which a lady and her cook were attacked with erysipelas and blood-poisoning shortly after occupying a house. Various alterations were made in the drainage in the absence of the family, but on their return the lady was again attacked with erysipelas, and shortly after other members of the household. Again alterations were made, and again the lady was attacked with erysipelas, and the housemaid with typhoid fever. An examination of the house by the author showed that an old stoneware drain in the scullery into which the sink formerly discharged, before it was disconnected, had not been removed, and though stopped with cement, the stopping was imperfect, thus allowing the air of the drain to enter the house. The author next considered the various ways in which foul air from faulty drainage inside the house passes to different parts, and pointed out the opportunities which were given for the passage of air from one part of a house to another, depending chiefly upon windows and fires; the latter, of course, mainly acting by drawing air through passages, staircases, and doors. But other channels must also be borne in mind; and an interesting account was given of the passage of foul air along bell-wire tubes, the proximity of the bell-pull to the fireplace giving an increased opportunity for air to be drawn from a distance to this part of a room. Channels for gas-pipes and for hot-water pipes also not uncommonly give facility for the admission of foul air. In connection with this part of the subject, a remarkable instance was given of a particular bed in a school, the occupants of which were constantly the subjects of slight attacks of pneumonia, with tendency to typhoid. In this case the foul air was conducted from a lavatory, where there was defective drainage up a staircase, and, impinging on the ceiling of the dormitory, was reflected on to the bed where the sickness occurred. An interesting account was given of the cause of the Duchess of Connaught's recent illness. Defective drainage was found in the basement of the house; and after numerous experiments, the means by which the foul air entered the duchess's bedroom were discovered. These showed that it was only when occupying certain positions in the room that she would be exposed to the influence of the foul air, while in bed she would escape. As a matter of fact, in twenty-four hours after sitting on a sofa in one of these exposed positions Her Royal Highness's symptoms fully developed themselves. These two

cases were illustrated by diagrams. The necessity of a thorough disconnection between the drains and the domestic water-supply was then dwelt upon, and the mistakes most commonly made in this particular pointed out.—In the discussion which followed the President, Dr. Buchanan, Dr. de Chaumont, Dr. Corfield, Mr. E. C. Robins, Dr. Bate, Mr. Jacob, Dr. Rogers, Dr. Poore, and Mr. Shirley Murphy took part.

MIDLAND MEDICAL SOCIETY.

An ordinary meeting of this Society was held in the Birmingham Medical Institute on Wednesday, November 22nd, 1882, Dr. Malins, President, in the chair.

Dr. Malins showed a large Cyst of the Broad Ligament successfully removed by Abdominal Section.

Mr. Kenneth Millican (Kineton) exhibited some specimens of Bacilli from cases of Diarrhoea which were found in the stools of patients affected during an epidemic. The motions were not unlike those of typhoid fever, and contained small gelatinous lumps. A cover-slip smeared with these lumps, dried and then stained with aniline blue, exhibited the organisms. An interesting therapeutical point was that the diarrhoea, which resisted all ordinary methods of treatment, yielded in about twenty-four hours to the internal administration of carbolic acid and terebene, the former being given in one and one and a half grain doses every two hours, the latter in doses of from five to ten minims.—Mr. Millican also showed a specimen of *Bacillus Anthracis*.

Dr. A. H. Carter showed specimens of the *Bacillus Tuberculosis* prepared by the method of Dr. Heneage Gibbs.—Mr. Millican referring to some remarks as to the diagnostic value of the bacillus tuberculosis, said he considered Dr. Heneage Gibbs' method absolutely diagnostic for the following reasons:—(a) It stained the bacillus tuberculosis clearly, and did not affect the organisms found in phthisical sputum. He had tried Ehrlich's method and several stains of his own, but found that, while they certainly brought out this particular organism, they obscured the diagnostic value by bringing out also the organisms and putrefactive bacteria. Having assured himself that these organisms were present in the sputum, he then used Gibbs' method, and found that only the bacillus tuberculosis appeared. (b) On employing Baumgartens's method—viz., immersion in a 33 per cent. solution of caustic potash—he found this rendered the bacilli visible; afterwards by staining with Gibbs' process it was found that all the organisms took the stain. (c) He failed to make Heneage Gibbs' stain dye the organisms from epidemic diarrhoea, stale sputum, and stale hay infusion until after they had been immersed in the 33 per cent. solution of caustic potash; they then stained readily.

Dr. Simon showed a series of living cases of Extensor Paralysis.

Dr. Savage showed two specimens of Double Pyosalpynx which he had recently removed from two young single women. There had been a long history of pain, and in one of the patients anæmia and a high temperature, 104°. The tumours were each about the size of an orange. During removal of the tumours rupture occurred, and there was a considerable escape of pus into the pelvis; this was cleaned out, and a drainage-tube inserted. The operations were not performed antiseptically. The patients did well.

The Notification of Infectious Diseases.

Mr. J. H. Palmer (Solihull) in moving the fol-

lowing resolution, "That this Society, recognizing the necessity for legislation to provide for the better notification of infectious diseases, is of opinion that the duty of making such notification should devolve upon the occupier of the house and not upon the medical attendant," said that the expediency of providing legislation for the better notification of infectious diseases had occupied the attention of the profession, with whom the idea had originated, and of the public. In many private Bills which had passed into law powers had been conferred upon sanitary authorities to enforce which no one would dare to attempt. The Bill introduced by Mr. Hastings was sound in its object but faulty in detail. The duty of making the notification was one which obviously devolved upon the occupier of the house. In the Bill brought in for Ireland the duty of notifying was rendered compulsory on the occupier and permissive on the part of the medical attendant; that seemed the prudent course. Mr. Hastings' proposal that the matter should go to a Select Committee was a fair one, and showed that Mr. Hastings was quite prepared to see the question discussed in all its bearings.—Dr. Griffiths seconded the resolution.—Dr. Alfred Hill in moving an amendment combated the objection raised by the opponents of notification by medical men, such as compulsion and its alleged consequences—viz., antagonism between the medical attendant and the medical officer of health, the inquisitorial character of the duties of the latter in some cases, and the spread of disease from concealment. He showed that in many towns where the Acts had been put in operation the evil predicted had not followed, and the best results had been obtained. Compulsion of the householder had been tried in Greenock for five years, and had failed to achieve the amount of good to be expected from a compulsory system of notification. Nothing but notification by the medical attendant, either with or without the same by the occupier, would be of use. He concluded by moving the following amendment:—"That this Society sharing the views of the leading sanitary authorities, that early notification is necessary for the control of infectious diseases, and having the benefit of the experience of the large number of towns which have already put the Compulsory Notification Act into force, is of opinion that every sanitary authority should possess parliamentary powers to obtain notification from both the medical attendant and the householder or person in charge."—Dr. Wilson (Leamington) seconded the amendment, and said there could be no doubt that outside as well as inside the profession there was a steadily growing conviction that no systematic or efficient control of dangerous infectious disease was possible without early notification, and that such notification could not be uniformly obtained unless under legal compulsion. It was quite true that the experiment had been tried in various quarters, and in a part of his own district, of entering into an agreement with medical practitioners to report all cases of certain specified diseases on payment of a stated fee; and though he admitted that the experiment, so far as his experience went, had succeeded admirably, he felt sure that it would not succeed in any locality of limited area and population where the medical officer of health was allowed private practice, and could thus enter into competition with his medical brethren. He felt convinced that there could neither be promptitude nor efficiency in notifying unless the medical attendant was made responsible, although he maintained at the same time that any measure would be faulty and one-sided if it did not render the householder liable to heavy penalties if he failed to report.—

Mr. Gamgee spoke in favor of the resolution.—Mr. Henry May (Aston) supported the amendment.—Mr. H. R. Kerr (Halsowen), while believing compulsory notification to be necessary, objected to the onus being thrown on the practitioner.—Mr. Hall Wright believed that in refusing to notify the members of the profession would be doing an injustice to themselves and to the public by shirking a responsibility that it was their duty to take.—Dr. A. H. Carter thought there was an official and a professional side to the question, and that the members of the profession had not been treated well in the matter. The Birmingham Town Council were about to apply for a Bill compelling professional notification, and he thought that a deputation should attend upon that body before the initiative was taken.—Mr. Palmer, in reply, stated that he regarded compulsory notification as the thin end of the wedge. The amendment was then put, and carried by a large majority, and subsequently as a substantive resolution.

CAMBRIDGE MEDICAL SOCIETY.

At the meeting on November 3rd, 1882 (Professor Humphry in the chair), the subject for discussion was "Sudden Death (irrespective of Hemorrhage) during Confinement, or within three weeks after—the Causes, etc."

In answer to a circular requesting members to inform the President whether they had seen any cases, and if so to give the particulars, thirty-five replies were received. A total of twenty-nine cases were supplied by fifteen persons; twenty-one members had not seen a case. Professor Humphry had made an analysis, and divided the cases into three classes—viz., of sudden death (1) before the birth of the child; (2) soon after delivery; (3) within three weeks after confinement. Under the first heading five cases were reported, in two of which death was apparently due to exhaustion from long and complicated labour. Fifteen cases were reported under the second heading: in two the cause of death was not apparent; in three the labour was tedious and severe; two were cases of inverted uterus; one case was marked by diabetic coma and one by albuminuria; three were cases of placenta prævia; in one case rupture of the uterus occurred; and in one parturition supervened during an attack of typhus. Under the third heading eleven cases were returned; nine of the deaths were attributed to embolism; in one case there was albuminuria, and in another apoplexy.

Dr. Stowers (of London) exhibited a male patient, aged twenty-eight years, who had been under his care eight months suffering from Acne varioliformis. The disease first appeared on the skin in front of each ear, and had throughout been almost entirely limited to the face, scalp, and upper part of chest. Deep punched-out scars, or pocks, marked the sites of the pustules, so that the deformity remaining was equal and similar to that of confluent small-pox. Several unsuccessful attempts at inoculation were made to test the character of the pus. The patient recovered entirely under the influence of increasing doses of arsenic, aided by the topical application, by puncture, of carbolic oil, thus supporting the belief previously held by Dr. Stowers that the affection was in no way related to syphilis.

NORWICH MEDICO-CHIRURGICAL SOCIETY.

THE second meeting of this Society was held at the Norfolk and Norwich Hospital on Dec. 5th, 1882, the President, Dr. Barnes, in the chair.

Dr. Eade showed a specimen of a Phelebolithe,

the size of a hazel nut. A lump had existed on the lower part of the right leg of a woman for thirty or forty years, ulceration occurred, and the concretion was discharged; it weighed twenty-nine grains. The portion insoluble in water consisted of phosphate of lime, with traces of phosphate of magnesia and some carbonates; the soluble portion consisting of the chlorides of sodium and ammonium, and some sulphates.

Mr. D. Day exhibited a Dissection of a Double Foetal Monstrosity, of which the following is a brief description. The heads and limbs are perfectly formed. The bond of union is the front of the thorax and upper part of the abdomen. The ribs are united on each side to a complete sternum, which is symmetrical; the lungs are normal; and there is one umbilical cord. The heart is single, in a single pericardial cavity; the auricles are distinct, the ventricles completely blended; the vessels at the base are quite distinct; and there are two inferior venae cavae. The diaphragm and liver are common to both. Close under the liver are two stomachs, the intestine beginning by a fusion of the two pylori; for sixteen inches it is single, it then branches into two, and the remainder of the intestines run a normal course. The umbilical veins divide as soon as they enter the abdomen, half going to each side.

Dr. Bateman showed a specimen of Ovarian Disease, complicated with Hydatids of the Liver. Against advice, the woman persisted in going to the w.c., and was there seized with an attack of syncope, from which she died.

Dr. Mallins recorded a case of Jaundice, caused by a round worm obstructing the common bile duct.

Mr. Lyddon reported a case of Removal of Foreign Bodies from the Ears after twenty years' impaction; from one ear a pearl button, and from the other an iron dress-hook, were removed by iridectomy forceps. No structural changes had taken place in either ear, and the hearing was perfect.

Mr. H. Turner read notes of a case of Rheumatic Fever which, while apparently progressing satisfactorily, terminated fatally in two hours, with cerebral symptoms (the patient was taking fifteen grains of the salicylate of soda every six hours). The cause of death was believed to be meningitis.

Dr. Eade also described three cases, with cerebral symptoms, he had seen in consultation about the same time (September), no cases of the kind having occurred in his practice for several years.

ACADEMY OF MEDICINE IN IRELAND.

A MEETING of the Surgical Section took place on Dec. 8th, 1882, Mr. J. K. Barton, President, in the chair. In the library a man who had been trephined for abscess on the brain was exhibited by Mr. Kilgariff, and various specimens by card by Messrs. Franks, Croly, A. Benson, Stokes, Wheeler, and Abraham. Mr. Wheeler's included an interesting cast of dislocation of the wrist, caused by the contracting cicatrix of a burn, and Mr. Abraham showed the sputum of bronchitis and phthisis, contrasted in reference to the bacilli. Mr. Barton then gave the inaugural address as president of the section, and referred to the Surgical Society which had lasted for the past fifty years and had now become merged in the Academy of Medicine. He dwelt on surgical clinical instruction in the Dublin Hospitals as compared with the continental system, and made some suggestions which he thought would be of advantage in elucidating some of the most difficult problems of surgery. Mr. Kilgariff next read a paper on the case of

trephining he had exhibited, which was followed by a communication from Dr. O'Reilly, of Trim, on a case of nephrectomy by right lumbar section. The patient, a girl, was admitted into Trim Union Hospital and died in forty hours after the operation, probably from shock. On removal the kidney weighed eight and a half ounces and contained an abscess from which a large quantity of pus exuded. The case was evidently one of primary tubercular disease of the organ. Mr. Knott read a paper on dissecting aneurism of the aorta, which some of the members considered should have been kept for the Pathological Section, and the proceedings terminated.

The first meeting of the Medical Section was held in the College of Physicians on Friday evening, Dec. 15th, 1882, Dr. William Moore, President of the King and Queen's College of Physicians, Ireland, occupied the chair as President of the Section.

The President delivered an inaugural address. Having alluded to the absorption of the Medical Society of the King and Queen's College of Physicians into the Academy of Medicine in Ireland as its Medical Section, he reviewed at considerable length the advances made in the diagnosis of disease, particularly within the last twenty-five years. He referred first to affections of the chest, the differential diagnosis of which was now well-nigh perfect. In certain cases clinical observations of the temperature had proved of great use, and the most recent advance was the demonstration by Professor Robertson of the germ origin of pulmonary tuberculosis. To Laennec was due the elucidation of cardiac diseases, and to Traube, in great measure, the knowledge of the relations which may exist between these and renal affections. The diagnosis of valvular diseases had become very exact, but the precise value of murmurs as regards diagnosis and prognosis was apt to be over-estimated. Nor was the diagnosis of abdominal aneurism always an easy matter. Great advances had also been made in the study of specific fevers, especially of the endemic fever of this country, enteric or typhoid fever. Again, much had been done in the localization of cerebral and spinal diseases, among the more interesting of this class of maladies being hysteria, hystero-epilepsy, and hemianæsthesia. As regards the treatment of some of these affections, he mentioned some remarkable instances in which good results had followed the practice of metallo-therapy.

Mr. Arthur Benson exhibited a case of well-marked Retinitis Albuminuria in a boy, aged sixteen, without constitutional disturbance; Dr. Charles F. Moore, a case presenting Neuralgic Symptoms in a man having remarkable patches of white hair, some of which were congenital; and Mr. Story a case of Double Zonular Cataract.

Dr. J. W. Moore exhibited by card specimens of Diphtheritic inflammation of the throat; and Mr. P. S. Abraham microscopic sections showing (1) diphtheritic deposit of muscular tissue of the pharynx; (2) mycelium of fungus; and (3) degeneration of muscular fibre in diphtheria.

Dr. Wallace Beatty read a paper on the Causation of Left-side pain, drawing special attention to a form not sufficiently recognized, which was due to fecal accumulation, and removed by getting rid of the accumulation. The pain was felt over the lower few ribs on the left side, was associated with extreme tenderness on pressure upwards of the tenth or eleventh rib, scarcely any pain being felt on pressure of these ribs downward, and was relieved when the side was pressed inwards with the flat of the hand. He explained its occurrence by the drag of a loaded colon on the pleuro-colic ligament; this constant drag setting up a state of

extreme irritability in the nerves of that ligament, so that a painful impression was carried upwards along the left lesser splanchnic nerve to the spinal cord, and was transferred by the law of irradiation of sensations to the tenth and eleventh left intercostal nerves.—Dr. Walter Smith said the pleuro-colic fold had not received the attention it deserved. It certainly was of considerable importance in the investigation of abdominal disease. Dr. Beatty's arguments were valid as explaining certain kinds of left-side pain, but did not explain all kinds.—Dr. Wallace Beatty did not wish it to be understood that he considered left-side pain was caused in every instance by fecal accumulation, but only in cases presenting the symptoms he had mentioned.

Dr. Walter Smith related two cases of Paralysis of the left half of the Velum Palati, and raised the question whether palatine paralysis was invariably to be regarded as a characteristic sequela of diphtheria, or whether it may not occasionally supervene upon non-diphtheritic forms of angina. Case 1 occurred in a young lady, aged twenty-four, and the paralysis developed six weeks after an apparently simple ulcerated sore throat, for which she had been treated by Dr. Smith. Case 2, a young lady, aged twenty-six, was affected with what was considered to be a simple relaxed sore throat unattended with ulceration. She remained in a weak and nervous condition, and shortly afterwards the left half of the palate was found to be paralyzed. In each case the symptoms were similar—viz., difficulty of swallowing, nasal twang in the voice, and regurgitation of fluids through the nose. Both cases recovered completely. Dr. Smith submitted that it was not unreasonable to hold that catarrhal sore-throat may now and then give rise to slight motor paralysis through partial implication of the nervous system or otherwise.—Dr. Henry Kennedy said that diphtheria might exist without exudation. He had seen such cases in which paralysis followed.—Mr. H. G. Croly said that the large majority of cases described as diphtheria were really cynanche.—Mr. William Thomson asked, if paralysis occurred in the palate as the result of specific inflammation, why similar effects did not follow in other parts of the body where nerve filaments were concerned.—Mr. J. W. Moore alluded to the specimen which he exhibited, describing it as one of phlegmonous erysipelas of the throat in which diphtheritic conditions had supervened. He believed that paralytic symptoms occurred only in true diphtheria.—Dr. Finney considered the fact that other diseases were associated with paralytic symptoms confirmed Dr. Smith's view.—Mr. W. Stokes doubted that paralytic symptoms followed inflammation other than those of a diphtheritic nature.—The President regretted that no information had been given as to the presence of albumen in the urine in Dr. Smith's cases.—Dr. R. A. Hayes mentioned in support of Dr. Smith's view a case in which chronic inflammation of the palate, resulting from excessive tobacco smoking, gave rise to paralysis of the palate.

Dr. Walter Smith, in reply, said that the paralysis in these cases might be the result of myelitis or of muscular degeneration. He answered Mr. Thomson's question by pointing out the rich nervous supply of the palate, and the muscles being open to attack from both sides.

The Section then adjourned.

—DR. DAVID W. CREEVER has been nominated to the Professorship of Surgery in the Harvard Medical School, rendered vacant by the resignation of Dr. Henry J. Bigelow.

(17)

THE ANNUS MEDICUS 1882.

Introduction.

We proceed to lay before our readers a history of the year 1882, not pretending that it is complete. As on previous occasions, we go at once to our duty without preface or comment on the general history of a year which, with all its faults, will not look badly in British history.

Anatomy and Physiology.

Before referring to a few of the more noteworthy of the facts which have advanced our knowledge of Anatomy and Physiology during the past year, it is with feelings of no ordinary emotion that we notice the death of Charles Darwin, the great naturalist, whose work, continued through a long period of bodily infirmity, has left a durable impress on the whole field of modern thought; who passed away in the spring at the ripe age of seventy-one, and who lived long enough to see that the calm and unimpassioned, yet logical mode in which he stated his opinions, and the vast array of facts resting on unimpeachable authority he brought to support to them, had converted to his doctrine many of those who by education and vocation were most disposed to ignore, scoff at, and oppose them. In the next place, it is fitting to express our deep feeling of regret at the loss science has experienced in the death of Professor Francis M. Balfour, of Cambridge, a brilliant follower of Darwin, and to pay a tribute of respect to the excellence of the work on Comparative Embryology, which he had only just completed, and which promises to be for a long time the text-book on this subject. The observations he had made are to a very large extent original, and though time has not yet been afforded to enable them to be corroborated by other observers, yet the care with which they were undertaken, the rare manipulative dexterity he possessed, and the acuteness of his perceptions, combined with the habitual caution with which he formed his opinions, render it probable that they will meet with very general acceptance. The statements made are everywhere well arranged and easily accessible to the student. The next works to be mentioned are the several splendid volumes of the reports of the scientific results of the *Challenger* expedition, to which we have on various occasions directed the attention of our readers, as containing an immense amount of original information upon the inhabitants of the deep sea, and many beautifully executed drawings of animals new to science, with descriptions by such men as Mosely, Haeckel, and others thoroughly versed in the anatomy and physiology of the animals of which they treat. There have not been many additions to the existing and well-known treatises on anatomy and physiology during the past year, though several new editions have appeared. Thus of the former we have only to enumerate Mr. Reeves' *Morphology*, a work of considerable originality and research. Dr. Mears has written a work on *Schematic Anatomy*, which is on a new principle, and presents some advantages to the learner.

The first part of a good system of Comparative Anatomy has been published by Wiedersheim, and the first fasciculi of *Treatises on Zoology*, by Lanesan and by Moquin Tandon, have been issued, the last, however, being a translation of a new edition of Claus, a work already well known. Amongst the new editions may be mentioned Quain's *Anatomy*, which has been considerably enlarged, and in which the Histology has been carefully revised by Mr. Scheffer, the Embryology and Development by Dr. Allen Thomson, and the Anatomy by Professor Thane assisted by Mr. Godlee, rendering it upon the whole the most complete work of the

kind in any language. A third edition of Professor Mapother's work on Physiology, revised by Dr. Knott, has appeared, and Dr. Dalton has issued the seventh edition of his excellent Physiology, which has the rare merit in physiological works of being somewhat less voluminous than its predecessors without losing in clearness and precision. A second edition has also appeared of Harris and Power's Manual for the Physiological Laboratory. Many important papers have appeared in the successive numbers of the *Quarterly Journal of Microscopical Science*, amongst which may be mentioned Pringsheim's and Lankester's Researches on Chlorophyll, Klein's article on the Lymphatic System, Walpole and Huxley on Saprolegnia in relation to the Salmon Disease, and Herbert Carpenter's notes on Echinoderm Morphology. In the *Journal of Anatomy and Physiology* the segmental value of the cranial nerves has been discussed by Dr. Milnes Marshall. The cerebral sinuses and their variations have been described by Mr. J. F. Knott, and the volume issued during the present year contains many valuable articles on comparative anatomy. The *Journal of Physiology* contains papers by Newell, Martin, and Sedgwick on the mean pressure and the characters of the pulse wave in the coronary arteries of the heart settling the question in favor of those who believe that the coronary arteries are injected during each systole of the heart and not during the diastole, and also an excellent paper by C. S. Roy, showing that the spleen performs rhythmical contractions independently of cardiac and respiratory movements.

In the "*Leçons sur les Modifications du Sang*," in which the changes presented by the blood under the influence of various remedies and therapeutic agents has been carefully investigated, Georges Hayem has made a substantial addition to our knowledge of this fluid. By giving a table of the number of blood-corpuscles in a cubic millimetre, corresponding to every number from 40 to 270 of blood corpuscles counted in a square of a hæmatocytometer, he has materially facilitated all calculations of the absolute number of the blood-corpuscles. Malassez has specially discussed the development of the red corpuscles in the medulla of the bones, and Mayet the spontaneous changes undergone by the colored corpuscles preserved in plasma without access of air; whilst Alexandre Schmidt has contributed to Brown-Séquard's *Archives* a résumé of the researches made under his direction at Dorpat upon the physiological and pathological action of the leucocytes of the blood, in which he still continues to maintain that the white corpuscles contain a ferment that plays an important part in the act of coagulation, and having separated this ferment he shows its effects when injected into the economy. Cadet, Bizzozero, Hart, and others have occupied themselves with the bodies named hæmatoblasts and with Dr. Norris' third or transparent corpuscles of the blood, with the result of showing that they are probably ordinary corpuscles partially deprived of their coloring matter or hæmoglobin. Bizzozero has suggested an instrument to which he has applied the name of hæmatocytometer in which the intensity of color and the degree of opacity are measured by the different thicknesses that must be given to a solution, or to a blood mixture, to reproduce a certain optical effect; the imitation of a test solution for color and the disappearance of a luminous point situated at a certain distance for the opacity.

Careful observations made by Vignol in Ranvier's Laboratory seem to have demonstrated that in the lower vertebrata the heart possesses a local motor and a local inhibitory centre.

Duclaux has written a work on ferments and their relation to disease. In this he treats of the nutrition and development of microscopic organisms, and gives some remarkable facts bearing on their growth. Thus, in the case of the aspergillus a sixteen hundred thousandth of nitrate of silver is sufficient to arrest its growth, whilst it will not grow in a vase of silver, though the quantity of metal dissolved is totally inappreciable to chemical tests.

The obscure subject of the dilatation of the bloodvessels under the influence of the nervous system, has been treated of at great length and with much ability by MM. Dastre and Morat, who have satisfied themselves that it is in most, if not in all, instances of a reflex character, the centre being in the spinal cord and medulla oblongata, the sensory being the afferent and the sympathetic nerves containing the efferent fibres, which directly induce the dilatation, and which emerge from the cord by the anterior roots of the spinal nerves, and then associate themselves with the sympathetic.

Dubar and Remy have studied the phenomena of absorption by the peritoneum, and have shown that albumen in solution is absorbed by the peritoneum without producing apparent change in that membrane, that the albumen so absorbed does not accumulate in the serum of the blood, and that it is well borne and inoffensive. They have further endeavored, by means of the injection of coloring agents, to follow the course of the absorbed material. The histology of the mammalian gastric glands and the relation of pepsin to the granules of the chief cells has been worked out by Langley with much success.

Honigsberg has compared the digestibility of meat in various conditions in artificial gastric juice, and finds that with an artificial gastric juice composed of five grammes of Witte's pepsin, dissolved in 1,000 cubic centimetres of water acidulated with one part of hydrochloric acid, raw meat yields 39.7 per cent. of peptone, boiled meat 26.6 per cent. and roast meat 48.0 per cent. The action in the stomach itself is undoubtedly far more complete, but the experiment is in favor of the digestibility of well-roasted meat. Schulze and Barbieri have demonstrated the presence of peptones in the juices of various plants, as in the potato and beet.

Vella has made intestinal fistulae, and then injected pilocarpine subcutaneously, which he finds possesses a remarkable power of inducing secretion of the intestinal juice. Experiments made with the juice so obtained emulsified fats, converted cane sugar into grape sugar, and digested proteids. It acts, however, differently from gastric juice on muscle. Gastric juice dissolves the perimysium first, and then the primitive fibre; whilst intestinal juice attacks the fibre first, and leaves the perimysium intact.

Goltz has continued his researches upon the brain, and shows that injuries of a severe character to the vertex (convulsions) of the brain in dogs produce not only diminished intelligence, but a remarkable change in their psychological character, harmless and good-tempered dogs becoming snarling and morose; whilst, if the occipital lobes are damaged, the animals preserve their good-tempered character, but their intelligence becomes much more seriously impaired.

Merschewski has experimented on the functions of the olivary bodies of the medulla oblongata, and has shown that after deep injuries to them rolling movements towards the injured side occur with nystagmus of the corresponding eye. He believes that they stand in close relations with the functions of the cerebellum. The structure of muscu-

lar tissue has been investigated by Hippolyte Martin, who regards the muscular fibril as composed like an amoeba or rhizopod, or leucocyte of granular protoplasm, but affecting the form of cylindrical rods, in which the proteic granules are of several species, and arranged in a determinate order. The dark discs are composed of two closely opposed granules at the extremities of the rod, and the space between them is occupied by three other granules, the centre one of which is larger than the other two; in moderate contraction these three granules appear fused together, whilst in great extension they appear as separate granules.

The duration of the latent period of the "tendon reflex" in the healthy adult has been carefully measured by Eulenbergh in healthy adults, and found to vary but little from 2-62 of a second. He regards it as something more than a mere reflex phenomenon, and endeavors to prove that it is of a complex nature. De Watteville appears, on the other hand, disposed to regard it as a direct contraction.

A very complete treatise has been published on the physiology of the muscles and nerves by M. Richet, which gives in a remarkably clear and orderly manner the chief facts that are at present known in regard to the relation of their important lesions, which M. Richet has himself done so much to elucidate.

We must not omit to mention that Professor Burdon-Sanderson has been offered, and has accepted, the important post of Professor of Physiology at Oxford, and whilst we trust he may long continue to occupy this distinguished office, we hope also that he will exert himself to lay the foundation of a good medical school, and at the same time gather around him a band of youthful and energetic workers, who may enable Oxford to vie with the great universities of the Continent.

Pathology.

In the department of pathology the year that is closing has been, on the whole, infertile. Isolated facts have been reported in their usual abundance, and even superfluity, but of new discoveries there have been few, and those, with one signal exception, of small importance. The year has been especially barren so far as English pathology is concerned. From the laboratories of neither England nor Scotland has any important work proceeded, and even from the Brown Institution, from which we have had such good work in the past, comes the sound of physiology rather than of pathology. The lectures on inflammation by Dr. Burdon Sanderson, and on Pulmonary Cavities by Dr. Ewart, deserve, however, especial mention, although, in the former, we are not carried far beyond our previous standpoint. Abroad, bacteria still absorb the energies of the pathologists of Germany and France, and the importance of the study has been sufficiently attested by the brilliant investigations which have added a new "household word" to the literature of pathology. Few recent discoveries have created a wider and more profound sensation than that of the tubercle bacillus, for which Koch certainly deserves the high credit he has received, although the discovery had been worked towards by many investigators, and was made independently by Baumgarten. The organisms of tubercle have given pathologists in all countries abundant work, and we may expect soon to have some definite facts bearing on its practical value, in addition to the technical facts regarding methods of observation which have been abundantly supplied. In other departments of bacterial pathology some new facts have been supplied, fewer in number, however, than in preceding years. Among them may be mentioned specially the researches of Birch-

Hirschfeld on the organisms associated with syphilis, and of Keating on those of measles, although the latter are scarcely more than a corroboration of the half-forgotten observations of Vacher and Braidwood. Of especial significance also is the fact announced by Fehleison, that the organisms of erysipelas are capable of giving rise to the disease after their separate cultivation. The remarkable observations of Laveran on the organisms which apparently constitute the active agent in the production of malarial disease, have been this year confirmed by Richard, and may perhaps excite more attention than they have hitherto received. Regarding other specific diseases the chief researches to note are those of Popoff on the changes in the brain in typhoid fever, and those of Elsenberg on the alterations which are produced in the salivary glands by rabies. In the region of general pathology, the subject of inflammation has been little studied. Besides the lectures of Burdon Sanderson, already alluded to, the most important researches are those of Spina, on the morphological changes presented by protoplasmic elements in the tissues, which have not the form of cells. Zuntz has investigated the cause of the increased oxidation which occurs in pyrexia, and believes that the facts he has ascertained regarding the action of curara must, to some extent, alter our views of the process. The subject of septicæmia has been somewhat neglected during the past year, and the work which has been done only serves to show how much more is needed. The experiments of Rosenberger, for instance, suggest that the relation of bacteria to this condition may be secondary and not primary, and are of special interest in connection with the facts which Rossbach has published, which apparently prove that, under certain circumstances, the organisms always present in the body may be the source of those associated with septicæmia. The general pathology of the blood has attracted little attention, nor can we expect new facts until there is more agreement regarding its constituents. We must not, however, omit to mention the researches of Hayem on the processes by which hæmorrhage is arrested, and on the peculiar "hæmatic crises" which occur during the course of many acute diseases. Apart from the question of its relation to bacteria, the pathology of tubercle has been the subject of many researches, and among those which deserve mention are that of Chiari on the hyaline metamorphosis which tubercle undergoes; the laborious investigations of Arnold on the minute structure of tubercle in various organs; the studies of its formation in the thoracic duct by Stilling, and in the veins by Weigert, and in the synovial sheaths of tendons by Terrier and Verhère. The facts described by Tappeiner regarding the production of phthisis in dogs by the inhalation of tuberculous sputum have been confirmed by Weichselbaum, although no new evidence of the contagiousness of phthisis in the human subject has been adduced. The observation of Friedlander may be regarded as demonstrating the frequent occurrence of organisms in connection with croupous pneumonia, although it still leaves undetermined their precise relation to the disease. The etiology of gastric ulcer has been studied experimentally by Aufrecht; the cause of the jaundice of newly born children has been investigated in a most able and thorough manner by Birch-Hirschfeld. No observations on the gastro-intestinal tract are more important than those of Nothnagel on intestinal catarrh and atrophy, which, although undertaken from a clinical standpoint, are of great pathological interest. The occurrence of compensatory hypertrophy of the kidneys has been demonstrated by Ribbert; and the researches of Aufrecht have thrown con-

siderable light on the pathogenesis of renal cirrhosis. Lastly, in what may be termed toxicological pathology, the most important investigations have been those of Cornil and Brault on the effects of arsenic and phosphorus, which have shown the identity of the changes produced by the two agents.

Therapeutics.

In the department of therapeutics there are many indications of vitality and of distinct reaction from that scepticism as to the use of medicine which followed, as effect follows cause, the rise and fall of homœopathy. The demonstration afforded by this exploded system, in its simplicity, of the strong recuperative powers of the system, naturally led physicians to question whether medicine could not be dispensed with altogether. But the answer to this question is no longer doubtful, and makes it clear that that practitioner will be at a great disadvantage who does not study the latest evidence on the physiological and therapeutical action of medicines. The growing care in investigating the action of drugs, and, we may add, the growing perfection of chemistry and of pharmacy, have shown that the most specific effects may be produced by drugs which a few years ago were not known to exist—witness the case of pilocarpine, of hamamelis virginica or its active principle hazeline, resorcin, etc. The old physicians used to speak of the effects and uses of opium, but recent chemistry and therapeutics have resolved opium into nearly a dozen substances with entirely distinct physiological effects, and capable of the most various use in the hands of the physician. This year has witnessed the introduction of a substance not originally in opium, but resulting from the action of hydrochloric acid on morphia—apomorphia. Few of the books on *materia medica* published this year contain any notice of it. Its use—for the discovery of which the profession is indebted to Dr. Gee—is that of an emetic to be introduced hypodermically. But it is in the smallest quantity powerfully effective—witness the remarkable case of brandy poisoning reported by Dr. Amand Routh in *THE LANCET* recently. The hypodermic use of quinine in ague has been shown in our columns by Professor Charteris, of Glasgow, and Dr. George Rankine, of the 6th Bengal Cavalry. The stimulating effect of fifteen minims of rectified ether administered hypodermically, and repeated, seemed to determine a favorable issue in a case of aconite poisoning detailed by Mr. Cecil A. Cooke. The hypodermic administration of the active principles of purgatives does not promise to supersede the ordinary use of laxatives. The antidotal action of the alkaline sulphates in poisoning by carbolic acid was illustrated by a case in the Royal Southern Hospital, reported by Mr. T. D. Ransford. Though some antiseptics are themselves shown to be capable of serious poisoning effects, the antiseptic and germicide theory still dominates therapeutics, not only in surgery but in medicine. Our pages are full of letters and other communications from practitioners alleging the efficacy of some antiseptic or other in zymotic cases. The local use of boracic acid dissolved in glycerine and water in diphtheria, by Mr. T. D. Harries, of Aberystwith, is a case in point. His conclusions are confirmed by cases reported by Dr. Goodhart to the Clinical Society, though he does not seem to have been aware of Mr. Harries's clear experience. Another case in point is the use of enemata of carbolic acid in typhoid by M. Ramonet; and yet others, are the successful administration of salicylate of soda in scarlet fever by Mr. James Couldrey, of Southorpe, near Brigg, where the disease has prevailed in a

severe form, and the use of salicylic acid in typhoid by M. Vulpian, reported to the *Académie Médicale*. The use of salicin and salicylates in acute rheumatism was the subject of a most elaborate series of papers, elsewhere alluded to, before the Medical Society. We can only here say that these remedies emerged from the discussion with enhanced reputation. It is noticeable, however, that Dr. Herbert Davies still prefers the blister treatment. The report of the committee of the Clinical Society on Rheumatic Hyperpyrexia, though chiefly clinical in its bearings, affirms the value of the prompt and early use of cold. The therapeutics of intestinal obstruction, not due to coarse mechanical conditions, are advanced by experience of the action of hyoscyamine in a case reported by Mr. Kenneth Millican, and by a growing use of belladonna, in cases where opium has failed or is contra-indicated. For the production of anæsthesia there is an increasing preference for ether as an alternative to chloroform. The action of drugs and the best mode of administering them are thus becoming more and more questions of the first importance in medical education and practice, in connection with that other great branch of therapeutics—the proper nourishment of the sick—which is receiving at present unprecedented attention.

Surgery.

The records of surgery during the past year are not marked by any striking novelty or great advance; nevertheless good work has been done in many directions. Sir Henry Thompson has recorded some instances of removal of tumours of the bladder through a perineal incision; and he advocates an exploratory incision in cases where the diagnosis is doubtful. He has also added another list of 101 cases of lithotripsy to the already large number recorded by him. Calculi have been removed from the kidney through a lumbar incision by Mr. Beck and Mr. Butlin, and other surgeons have recorded cases in which the kidney was examined with a needle through a lumbar incision without discovering a calculus; and it has been shown that this operation is practically free from risk. A considerable number of nephrectomies have been put on record by surgeons at home and abroad; and more than one lively discussion at the Societies has shown how great an interest is felt in the question as to when and how such a formidable operation should be undertaken. A somewhat allied subject—i.e., splenectomy in cases of leucocythæmia—has been discussed by Mr. Herbert Collier and Mr. Warrington Haward; the arguments of facts seems at present to be conclusive in condemning this proceeding. Numerous facts in abdominal surgery, which the greater differentiation of our art seems to be gradually (and we think regrettably) separating from the field of surgery proper, have been from time to time recorded in our columns; we will therefore leave the discussion of oophorectomy, chylocystotomy, and other performances, the very names of which are dreadful, for mention in another paragraph. Mr. Whitehead's method of excision of the tongue has been practiced and commented upon by several surgeons; there has been some diversity in the expression of opinion, but on the whole we gather it to be favorable. A novelty in the treatment of empyema has been suggested by Mr. R. W. Parker, who proposes to introduce purified air by a second puncture during thoracocentesis to replace the fluid which is withdrawn; but little opportunity has at present offered of putting his suggestion to the test of experience. Mr. Thomson, of Dublin, tied the innominate artery, and it appeared for a time as if the case were likely to prove successful;

but this hope was not realized. Mr. Holms recorded a list of cases in which the theca vertebralis was injured. Mr. Gould and Mr. Clutton have again raised the question of the treatment of spina bifida by reporting successful cases in which Morton's method had been employed, and the subject has been referred for investigation to a committee of the Clinical Society. A very remarkable lecture was given by Sir James Paget at the Royal College of Surgeons, on "Some Rare and New Diseases;" it was the first of an annual series of lectures founded by the widow of the late Mr. Bradshawe, of Reading, and was equally interesting from its novelty and suggestiveness. A warm discussion has been carried on with respect to the merits of the different anæsthetics commonly employed. At present the balance of opinion seems to be in favor of ether, but there are not wanting surgeons of high authority who maintain that we have not yet heard the last of this question. Several new materials have been introduced during the year as dressings, all of which remind us that, after all, the main question which is fermenting in the surgical mind is that of antiseptics; with some the question is as to the advisability of employing the antiseptic system at all, but with most it has resolved itself into the best means of putting it in practice. Amongst the materials referred to may be mentioned the boroglyceride of Professor Barff, and the salicylic silk of Mr. McGill, of Leeds; while the dangers and advantages of iodoform have also been brought prominently forward. Two Scotch surgical chairs have been vacated owing to the death of Professor Spence and the retirement of Professor Pirrie; the latter, however survived his retirement not more than a few weeks. A hot contest took place for both of these appointments, with the result that Mr. Chiene obtained the Edinburgh and Mr. Ogston the Aberdeen professorship.

Obstetrics and Gynecology.

In the department of Obstetrics and Gynecology the year has not been unproductive. Extra-uterine pregnancy, and its treatment by abdominal section, has been discussed by Mr. Knowsley Thornton and Dr. Goodell; while its treatment by electrolysis has been shown by Landis to be in some cases attended with satisfactory results. The occurrence of cardiac murmurs in the puerperal state has been studied by Dr. Money, who read an able paper on the subject before the Royal Medical and Chirurgical Society. Matthews Duncan has collected a number of cases of puerperal diabetes, and written the history of that perhaps "new and rare disease," in so far as it is at present possible. A new work on Midwifery by Lusk, and new editions of Playfair and Speigelberg's well-known works have appeared during the year. Lacerations of the cervix and Emmett's operation have been discussed, but we remain much in the dark with regard to the place occupied by these lesions in the production of suffering. The operation is regarded by some as one of the greatest and most beneficent additions to modern surgery, while others regard it as unnecessary meddling. Battey's operation has attracted a good deal of attention; some operators appear to meet with a large number of cases which call for its performance, while others see such cases extremely rarely. The operation is one whose influence on the female economy are evidently but imperfectly known, and the facts bearing upon this point published during the year have thrown but little light upon it. Garrigues has written an elaborate paper on the Diagnosis of Ovarian Cysts by means of the examination of their contents. Displacements of the uterus have not been neglected. Vedeler has published statis-

tics on a large scale showing the position of the uterus in healthy women, and these appear to have proved most damaging to the views of the mechanical school of uterine pathology. Herman also issued a paper on Backward Displacements of the Uterus, in which he attempted to show on anatomical and clinical grounds that retroflexion and version, as such, were of no consequence. Macan, in Dublin, has reproduced Schultze's views with regard to Antelexion. All this appears to point to the conclusion that the mechanical view of diseases of the uterus will in the future be tested with far more severity than hitherto, and that if it is to maintain its hold on the profession, more, and more scientific, evidence in its favor will be demanded. There are not wanting signs, both here and in America, that this view has been developed to its utmost limits, and that the pendulum is about to swing in an opposite direction. Dr. Fordyce Barker read an excellent paper on Leucorrhœa, its constitutional causes and therapeutics, before the American Gynecological Society, which is of the highest value, and which is sure to have a healthy influence on specialism in gynecology. New editions of the work of Spencer Wells on Ovarian and Uterine Tumours, and of Graily Hewitt's Diseases of Women, and an English translation of Courty's Diseases of Women by Miss Maclaren, have appeared.

Ophthalmology.

The completion of the great work of Graffe and Saemisch on the Anatomy, Physiology, and Pathology of the Eye, which is an encyclopædia in itself, seems to have practically prevented the appearance of any large work during the past year or two either in this country or abroad. The only exceptions we have to record are the systematic treatise on Diseases and Injuries of the Eye, by Dr. Wolfe, of Glasgow, which is a good text-book, and is illustrated by many colored lithographs, and the less complete but still carefully drawn up "Abhandlungen aus dem Gebiete der practischen Augenheilkunde" of Stellwag v. Carion, assisted by Wedl and Hampel. A new journal the *Zeitschrift für vergleichende Augenheilkunde* has been commenced. It is well supported, contains some excellent papers, and will fill a place that has too long been vacant. Masselon has published a small but convenient work of reference on the refraction, selection of glasses, perception of colors, visual field, and movements of the eye, under the title of "Examen Fonctionnel de l'Œil." Féré gives the results of his clinical observations in a work on crossed amblyopia and hemianopsia, under the title of "Troubles Fonctionnels de Vision." A very complete treatise on Sarcoma of the Uveal Tract has been written by Dr. Ernst Fuchs. A translation of M. Dagnenet's "Manuel d'Ophthalmoscopie," by C. S. Jeaffreson has appeared, and in addition to these several well worked up hospital reports have been published, notably that of Dr. Albert Mooren, of Düsseldorf, who, under the title of "Fünf Lustren Ophthalmologischer Wirksamkeit," has almost compiled a treatise on diseases of the eye, illustrated by the practice of his hospital. Mr. Nettleship, of London, and Dr. Williams, of Harvard University, have published new editions of their useful works, bringing them well up to modern knowledge, Dr. Williams' work being so much enlarged as to be practically a new treatise. A new journal, the *Revue Générale d'Ophthalmologie*, under the direction of Professor Dor, of Lyons, and Dr. Meyer, of Paris, has been commenced, and is well supported. The Ophthalmological Society has held its meetings with regularity under the able guidance of Mr. Bowman. The genial manners, the large views, and vast ex-

perience of Mr. Critchett, who would probably at no distant date have succeeded Mr. Bowman in the presidential chair, and whose death the members of the Society deplore, will be long held in remembrance. The histology of the optic nerve has been studied by Dr. Bergen, who has been unable to discover the direct communication observed and described by Leber, between the capillaries of the optic nerve and of the choroid. Robinski has investigated the structure of the lens; Aeb, the histology of the canal of Petit, and the Zonule of Zinn; Preiss, the lymphatics of the cornea; Wolff, the nerves of the cornea; Heisrath, the drainage system of the anterior chamber of the eye. Charpentier has contributed some papers on the differential sensibility of the eye, and he, Jaeger, Magnus and others have written on the sense of color. The use of the spray in operations on the eye seems to be spreading both in France and Germany. It will probably prove useful in cases of enucleation and abscission, but it is not well adapted for cataract operations nor for iridectomy. Many papers have been published on purulent ophthalmia, notably those of Haussmann, Abadie, Bailly, and De Wecker, and evidence appears to be accumulating that cases of blennorrhœic and gonorrhœic ophthalmia, and of suppurative keratitis, are in many instances attributable to, or, at least, associated with the presence of, certain micrococci and spores of fungi, such as the aspergillus, a subject that has been well worked out by Leber, of Berlin. The employment of homatropin as an agent capable of effecting dilatation of the iris, without the persistent effect of atropin, has come into general use, and pilocarpine has been shown to be not only a valuable and effective remedy in various diseases of the eye, but that it is an excellent antidote to the effects of atropine. Knapp has collected a series of interesting cases in which foreign bodies have been tolerated in the fundus oculi, showing that it may not always be requisite in such accidents to proceed at once to enucleation, especially if the foreign body be small. Fedor Krause has given a good account of the pathological changes occurring in sympathetic ophthalmia, showing that the changes proceed chiefly along the ciliary nerves. Dr. Ayres has written a paper on the same subject, recording cases which seem to show that the changes are progressive along both the optic and the ciliary nerves. But the number of memoirs and original communications on the pathology and treatment of diseases of the eye is immense, and furnishes sufficient evidence of the attractiveness of the diseases of the eye as an object of study.

The Royal College of Physicians.

At the Royal College of Physicians several important questions both of policy and ethics have been discussed. One recent and significant act of the College has been to appoint a sub-committee to confer with delegates of the College of Surgeons with a view to the formation of a Conjoint Board consisting only of these two bodies, leaving out the Apothecaries' Society. In this course the College is only accepting a proposal originally made by the College of Surgeons in May, 1881. The prospect of legislation makes the movement less opportune and important. One noteworthy step the College has taken throughout the year is the agreeing to the moderately worded resolution of Dr. Wilks with regard to homœopathy. The report on this discussion, however, which appeared in our columns, led to an amusing self-assertion of dignity on the part of the College Censors. Whether from the observance of excessive prudence, or from a jealous regard for its fancied importance, it was declared that henceforward the

proceedings of the College were to be considered as private communications. Considering that for some years past the proceedings have been duly reported, unless an intimation to the contrary had been preferred by the President, the action taken by the Censors must be considered a retrograde one. Another important question, on which the College has given an uncertain sound, has been that of professional advertising. It need only be said that while the London College was content with reprobating the practice of extensively advertising, the Irish College censured the advertising of medical publications in the lay press absolutely. There can be little doubt that if Fellows of the Royal College of Physicians advertise their books in the lay press they do a great injustice to the bulk of general practitioners whose patients they entice to their own consulting rooms. The Irish Fellows in this question have shown a higher sense of justice and less greed than the representatives of the London College. Another fact may be noted—namely, that the College this year has been obliged to appoint examiners in Anatomy, Physiology, and Chemistry outside the circle of its Fellows. The Gulstonian Lectures of the year were delivered by Dr. W. Ewart, "On Pulmonary Cavities; their Origin, Growth, and Repair." The Lumleian Lectures, by Dr. J. Burdon Sanderson, treated of Inflammation; whilst Sir Joseph Fayrer, in the Croonian Lectures, took the Climate and Fevers of India for his subject. The Bradshawe Lecture was delivered by Dr. E. Long Fox: "On the Influence of the Sympathetic System in Disease."

The Royal College of Surgeons.

The year has been an eventful one for the Royal College of Surgeons. Beginning with the extended examination in Medicine and the new examination in Midwifery for the final membership, and ending with the appointment of delegates to meet a sub-committee of the Royal College of Physicians, to consider the possibility of establishing a complete conjoint medical and surgical examination, the year has been full of incidents affecting not only the welfare of the College, but also the interests of medical education. At the meeting held on January 12th the principle of a preliminary scientific examination was approved, on the condition that such examination should be passed before the beginning of the professional curriculum. In March a standing rule was adopted that a candidate referred on the primary membership for three months, should before re-examination produce a certificate from his teachers of having pursued his anatomical and physiological studies during that period to the satisfaction of his teachers, whereas candidates referred for six months should, in addition, produce evidence of having dissected for three months. In April the Council adopted the principle that after October, 1882, an interval of two years should elapse between the passing of the primary examination for the diploma of member and admission to the final examination, except in certain special cases. In May the report of the Joint Committee on the proposed institution of an examination in elementary anatomy and physiology was presented to the Council. The committee recommended that the proposed examination should be held at the various medical schools, and conducted by the teachers, instead of at the College. At the meeting held in June it was resolved to call the attention of the authorities of the several recognized schools to the proposed regulation, and to invite the teachers of anatomy and physiology to confer with the Joint Committee of the College as to the mode of carrying out the proposed examination. This conference was held on

June 26th, and the principle of holding an elementary examination in Anatomy and Physiology at the schools was, after a long and full discussion, almost unanimously adopted, with the condition that six months should elapse between the Elementary and the Primary Examinations. On July 6th Mr. Marshall and Mr. Power were re-elected members of the Council, and Mr. Croft was elected a member of the Council, and in the following week Mr. Spencer Wells succeeded Sir Erasmus Wilson as President of the College, Mr. Marshall and Mr. Cooper Forster being elected senior and junior Vice-presidents respectively. The vacancy in the Court of Examiners, caused by Mr. Birkett's retirement, was filled up in October by the election of Mr. Bryant. In July Mr. T. M. Stone resigned the post of Clerk, after a useful, valued, and honorable service of fifty years at the College. On Dec. 14th seven delegates were appointed, as hinted above, to meet and confer with a sub-committee of the Royal College of Physicians on the possibility of a combination of the two Colleges for the establishment of a complete conjoint medical and surgical examination. On the 13th Sir James Paget delivered the first Bradshaw Lecture at the College "On some New and Rare Diseases." This lecture is published in *extenso* elsewhere in this number. It may be mentioned that during the year an attempt has been made to form an Association of Fellows, but as some of the promoters have not hesitated to avow a wilful spirit of antagonism to the College, the attempt has hitherto received no countenance from the principal Fellows.

Army and Navy Medical Departments.

During the past year no change has taken place in the organization of the Army Medical Department. At the half-yearly examination for admission into the service a sufficient number of candidates presented themselves to make it really competitive, and to show that the conditions of service at present in force are acceptable to the profession. In the beginning of May Sir Wm. Muir retired from the post of Director-General, and was succeeded by Dr. T. Crawford, who was up to that time Principal Medical Officer of the troops in India. His appointment was regarded with much satisfaction by the Department. On the outbreak of the war in Egypt Dr. Crawford was called upon to organize the medical service for the force to be employed there, which he did in a manner that met with the full approbation of the military authorities. When, from unforeseen changes in the military operations, difficulties were experienced in bringing up to the front those supplies of medicines and medical comforts which had been provided on a liberal scale, an attempt was of course made to show that this was owing to the defective organization of the Department and the want of foresight on the part of the heads of the medical service. These charges were supported by statements of a very unscrupulous character, and were, we fear, in many instances put forward for the purpose of throwing discredit on the present system of departmental organization. Many of these statements have already been disproved by the evidence of eye-witnesses, and we have no doubt that the inquiry now being conducted by the Committee appointed by the Secretary of State for War will completely remove the odium which has been attempted so unfairly to be cast upon the medical service. The military authorities, both at home and in Egypt, have borne testimony to the praiseworthy manner in which the medical officers discharged their duties, and the sympathy of their professional brethren in civil life was well manifested by the banquet given to celebrate

their return to England on the termination of the war.

An important alteration was introduced into the Indian Medical Service during the year by the adoption of the station hospital system instead of the regimental. This was carried out under the supervision of Surgeon-General Crawford before he left India to take up the appointment of Director-General. The Indian Service furnished the necessary medical staff for the contingent employed in Egypt, and the arrangements were carried out in a most satisfactory manner.

There has been no change in the organization of the Naval Medical Service during the year. The Order of Knight Commander of the Bath has been conferred on Mr. J. Watt Reid, the Director-General of the Department.

It is satisfactory to find that for all the three branches of the public service an adequate supply of candidates has been forthcoming at the competitive examinations; and it is also matter for congratulation that in the distribution of honors for service in Egypt the medical officers have not been left out, as has happened too often in previous wars, but have received a fair share of the promotions and decorations.

Mirror of Hospital Practice.

Thanks to the generous co-operation of the physicians, surgeons, and their assistants attached to the various hospitals and dispensaries through the kingdom, we have been able to publish in our "Mirror of Hospital Practice" a large number of selected cases, presenting aspects of clinical, pathological, and therapeutical interest. The cases have not only been instructive in themselves, but have afforded a tolerably accurate indication of the progress of medicine and surgery. Out of the records many examples may be found of things both "rare and new." Where every case presents some interest it is difficult to select instances for special mention. Among the medical cases we may, however, cite:—rupture of lung, pneumothorax, paracentesis, recovery, under the care of Mr. Gould at Westminster Hospital; hydronephrosis treated by aseptic incision by Dr. Tuekwell and Mr. H. Symonds, of the Radcliffe Infirmary, Oxford; spontaneous rupture of the heart, under the care of Dr. Coupland, of the Middlesex Hospital; ulcerative endocarditis simulating typhoid fever, under the care of Dr. Sturges, of the Westminster Hospital; rupture of liver, thrombosis of the hepatic veins and embolism of a branch of the left pulmonary artery, under the care of Mr. Makins, at the Seamen's Hospital, Greenwich; rupture of an aneurism of the basilar artery, under the care of Mr. C. J. Wright, of the Leeds Public Dispensary. Among the surgical cases may be mentioned:—transfixion of neck by a walking-stick, under the care of Mr. Davies Colley, of Guy's; adherent stone in the bladder, forming after injury to spine, under the care of Mr. Henry Smith, of King's College Hospital; successful removal of large uric acid stone, weighing eight ounces, by literal lithotomy, under the care of Dr. Underhill, of Guest Hospital, Dudley; compound dislocation of the sixth from the seventh cervical vertebra without fracture, under the care of Dr. Whippam, of St. George's Hospital; dislocation of the fifth cervical vertebra, reduction and recovery, under the care of Mr. Ceely, of the Royal Bucks Infirmary. Among the curiosities may be mentioned a case of eyelashes in the anterior chamber of the eye, the result of a stab, treated by Mr. Williamson, of the Newcastle-on-Tyne Infirmary, and a fish-hook successfully removed from the oesophagus by Dr. Goldsmith, of the Bedford General Infirmary; excision of the pyloric end of the

stomach for carcinoma by Mr. Sydney Jones, of St. Thomas's Hospital.

The Medical Societies.

At the various medical societies of the metropolis the year has not been very eventful. There have been no great debates in stirring controversies, but there has been the same steady pursuit of science in the records of cases of disease, of the results of operations, of pathological research, and in the general routine of useful work that renders the meetings of these bodies so attractive and fruitful. Commencing as usual with the Royal Medical and Chirurgical Society, we find this old-established and somewhat conservative body becoming alive to the fact that for some reason or other its meetings were losing much of their former popularity. In point of numbers the Society was never richer, but yet the Fellows failed to appear at the meetings and share in the debates, the contributions even became scanty, and rumor ran that the Society's younger rivals were pressing it rather hardly. However this may be, the changes that have been introduced—minor as they are in importance—during the past few months may have considerable effect in increasing the attendance and interest in the Society's meetings. Professor J. Marshall succeeded Dr. Barclay in the presidential chair, and his first duty on taking office was to move an address of congratulation to Her Majesty on her providential escape from the attempt on her life. The papers read before the Society have, many of them, led to animated debate, and some have enunciated new principles that may become established. As in other Societies, so here, surgery predominated. Mr. Bryant relating his successful case of Colectomy for Cancer, a subject expanded more fully in the recent paper contributed by Mr. Treves on Resection of Portions of the Intestine. Sir H. Thompson contributed a successful case of Removal of a Tumour of the Bladder by Perineal Section, and the same surgeon will shortly communicate another paper on this subject to the Society. Mr. Henry Morris's paper on Dislocation of the Hip-joint was another which aroused discussion, and so did Mr. Parker's proposal to employ intra-thoracic injection of air as an aid to the evacuation of certain forms of empyema. Other papers, of a more elaborate nature, were the researches of Drs. Ringer and Sainsbury into the action of Soda and Potash Salts, that of Dr. Champneys into the production of Mediastinal Emphysema following Tracheotomy, and that of Dr. Warner upon the Postures of the Hand as indications of Cerebral Action. Sir James Paget also contributed a further series of cases of the remarkable condition to which he has given the name *Osteitis Deformans*. One of the innovations referred to above has consisted in the exhibition of anatomical and other specimens collected from various sources in illustration of the subject of the evening; and in that way demonstrations of bacterial organisms, of entozoa, specimens of cranial and cerebral disease producing epilepsy, and of forms of intestinal stricture, have successively taken place, adding much to the interest and value of the meetings.—The Pathological Society has, we believe, managed to deal with more subjects than occupied it in any previous session; the specimens are so numerous, and the communications accompanying them are often so concisely and tersely made, that not only is much work got through, but also, we fear, there is less actual debating than in former years. This is to be regretted, for not seldom the most interesting facts are brought out by discussion. We are pleased to observe that the Society is receiving several contributions in comparative

pathology, owing mainly to the facilities afforded by the Zoological Society to certain members of the former body in making post-mortem examinations upon animals. We look forward to much valuable information being thus furnished to pathology, and cannot forget that Dr. Crisp, whose death recently took place, was the pioneer in this special department in the Society. By the death of Dr. Peacock the Pathological Society lost a former President, and one of the most constant contributors to its Transactions.—In connection with the sister Society—the Clinical—it is fitting also to mention that the revered physician whose loss is still fresh in the memory, Sir Thomas Watson, was the first occupant of the Presidential chair fifteen years ago. The Society has now a well-established position, and attracts many valuable communications. Amongst the subjects more particularly discussed within it during the past year were Nephro-lithotomy in papers contributed by Messrs. Beck, Butlin, and Haward; Nephrectomy by Dr. Goodhart and Mr. Golding-Bird, Dr. Barlow and Mr. Godlee, Mr. Marsh and Mr. J. E. Adams; whilst other subjects in abdominal surgery—e.g., splenectomy by Mr. Haward, and abdominal section for intussusception by Mr. Godlee, deserve prominent mention as indicative of the growing boldness of surgeons in this direction. The subject of Myxedema—a condition that still continues to excite clinical inquiry—was also thoroughly discussed at this Society early in the year. An elaborate Report upon Hyperpyrexia in Acute Rheumatism was presented by a Committee of the Society; it dealt exclusively with the clinical aspect of the subject, the Committee not attempting to frame any hypothesis upon its pathogeny.—The chief subjects debated at the Obstetrical Society have been Dysmenorrhœa on two occasions—one in a paper on its Treatment by Dr. Godson, and the other on its Nature by Dr. John Williams. A communication by Dr. Playfair upon Emmet's Operation also gave rise to considerable discussion.—The Medical Society of London has been the medium for several excellent papers, mostly of directly practical importance. The discussion upon the Salicylate Treatment of Rheumatism was prolonged into the present year, and occupied several meetings. Mr. H. Morris read a valuable paper upon Ichthyosis and Epithelioma of the Tongue; Mr. Bryant contributed a case of Gastrostomy for Cancer of the Esophagus; Mr. Gould advocated the Complete Removal of Axillary Glands in Mammary Cancer; Mr. R. Harrison spoke of the early treatment of Prostatic Enlargement; Mr. S. Gamgee upon Treatment of Wounds, and Mr. K. Thornton upon Nephrectomy. Indeed surgical communications were decidedly the more numerous, but amongst the medical subjects may be cited Dr. Jackson's paper on a case of Cortical Tumour of the Brain, and Dr. S. Mackenzie's upon the treatment of Chronic Dysentery by injections of nitrate of silver. The Lettsomian Lectures at this Society were given by Mr. Royes Bell upon Diseases of the Testicle; the annual oration was delivered by Dr. Symes Thompson, and the Fothergillian Prize was awarded to Mr. Dolan for his essay upon Whooping-cough.—The Ophthalmological Society entered this year upon its third session. It has found it necessary to add to the number of its meetings, which are so well attended and so amply furnished with good material that the *raison d'être* of the Society is quite proved. Mr. Bowman continues President; but the Society has had to lament the loss of one of its Vice-Presidents, Mr. Critchett, who took the chair at the closing meeting of the session last July, when a debate upon sclerotomy, continued over two evenings, took place.—Of

other Societies, the Hunterian, Harveian, Epidemiological, the Society of Medical Officers of Health, and others, it must suffice to say that there has been no lack of activity within them. At the Harveian Mr. H. Power was appointed lecturer, and he chose for his subject Ophthalmic Surgery in relation to General Practice. This year has also seen the inauguration of the West London Medico-Chirurgical Society, to meet a want in a large and populous district of the metropolis, and the meetings, we understand, that have already taken place have been thoroughly successful. A Dermatological Society has also been formed during the year; but its promoters have wisely decided to limit its numbers, and to conduct its meetings in a less formal manner than is usual. From all these and kindred gatherings of men engaged in one pursuit—that of honest inquiry after truth with a view to combat disease more thoroughly—there must be much to be gained, and in proportion as the value of these Societies is appreciated will their influence on the advance of medical science be extended. In one important particular we seem to notice a change in the character of the communications made to these Societies: there is far less of the speculative and theoretical, and more of the directly practical—a change which completely confutes the apprehensions of those who used to fear that with the growth of its science the art of medicine would decline.

The Medical Council.

The Medical Council met on June 27th, and did not rise till July 8th. One of its chief acts was to deliberate on the conduct of Mr. Murdoch, L.R.C.P. Edin., and L.S.A., in employing unqualified assistants and placing them in charge of dispensaries at a distance from his own house, to attend patients. It was further alleged against Mr. Murdoch, that he had allowed such assistants to sign his name to a false certificate of death. The latter charge was not sustained, but the Council regarded the facts in the first charge so seriously as to find Mr. Murdoch guilty of "infamous conduct in a professional respect." As this was new action on the part of the Council, and Mr. Murdoch had undertaken to discontinue the practices complained of, he was not punished by having his name removed from the Register. The Council appointed a committee, under the presidency of Dr. T. K. Chambers, to consider the abuses connected with unqualified assistants. The Council discussed and in the main approved the draft of a Bill to provide for the Education and Registration of Midwives. Its chief work, however, during the long session was the consideration of the Report of the Visitors of the Medical Corporations of the United Kingdom. The eminence and earnestness of the Visitors—Professor Gairdner, Mr. Teale, and Mr. Stokes—and the scale upon which their work had been done, excited the interest of the profession. There has never been such a comprehensive visitation of the Bodies as by these gentlemen. There was a marked effort to be faithful in the discharge of their duties, slightly spoiled, perhaps, by the desire to say nothing unpleasant. Certain conclusions and recommendations were formulated by Mr. Teale, which became very much attenuated, however, by discussion. The Council has an impossible task in trying to supervise and regulate so many examinations. The task is not only impracticable—it is very expensive. This particular Visitation is said to have cost £1,500.

Medical Associations.

The British Medical Association celebrated its fiftieth anniversary fitly at Worcester, under the presidency of Dr. W. Strange, who did great jus-

tice to the medical heroes of the last half century, notably Dr. Charles Hastings and his coadjutors in the foundation of the Association, and to the founder of this Journal as the great iconoclast of medical abuses and monopolies. The address in Medicine was delivered by Dr. Wade, and that in Surgery by Mr. Stokes, of Dublin. Dr. Flint, of New York, delivered a suggestive address on the self-limited duration of phthisis.

A very notable event in the year is the formation of a Society to promote the advancement of medicine by encouraging research. This is by no means a purely medical Society. Though including Sir Wm. Jenner, Sir James Paget, Mr. Spencer Wells, and other representatives of the profession, it also includes men like Professor Tyndall, Sir John Lubbock, and many other laymen who see the beneficent nature of medicine even when it sacrifices a rabbit or a dog to save the lives of men and animals on a large scale.

Medical Politics.

The great event of the year in the matter of medical politics is the appearance of the Report of the Royal Commission on the Medical Acts, recommending changes in the organization of the Medical Council and of the licensing boards in the direction long desired by the public and the profession. This Report shows a natural disposition on the part of the Commission to judge the medical authorities generously, but it nevertheless shows equally a perception of the defects of the existing system. Clauses 5 and 6 of Part I. of the Report are as follows:—

"On the other hand, it has been stated in evidence, and especially by witnesses who have been engaged in private tuition, that not only do the diplomas and degrees of these medical authorities imply very different standards of skill and knowledge, but that in some cases the possession of a diploma affords no guarantee that the practitioner holding it possesses a competent knowledge of medicine, surgery, and midwifery. Several distinct causes appear to us to lead to this result, such as the imperfections and low standard of some examinations; the fact that some examinations are injudiciously divided into parts, the first part of the examination of one Corporation being accepted by another, as in the case of the Apothecaries' Hall of Ireland and the Edinburgh Corporations; to which may be added the unsatisfactory manner in which the examiners themselves are in some instances appointed, as appears from the evidence laid before us by the representatives of the two Societies of Apothecaries."

Other defects in the existing licensing system are brought out. Certain bodies are specially mentioned by the Commissioners, whose examinations, by a notable concurrence of opinion among the witnesses, are considered unsatisfactory. These bodies are the Apothecaries' Societies, the Edinburgh College of Surgeons, and the Glasgow Faculty of Physicians and Surgeons. The system of the Edinburgh College of Surgeons for creating Fellows, which is practically a system of purchase, was brought out in evidence before the Commission, and was little improved by even Mr. Spence's defence of it. Similarly, in regard to the Medical Council, the work it had done was admitted liberally, and its failures were freely implied in the excuses suggested for its not doing better, and in the suggestions for a radical change in its constitution. The main proposals of the Commissioners are:—

"That there shall be one Medical Council. That in each division of the kingdom there shall be a divisional board representing all the medical authorities of the division, whose duty it shall be

to appoint a certain number of persons to be members of the Medical Council, to appoint examiners for the divisional board examinations, which alone are to admit to the Register," etc.

If legislation takes place on these lines, as we have reason to hope it may, there will be a Medical Council of eighteen members instead of twenty-four, and three licensing bodies instead of nineteen. The Council, moreover, will be no longer a weak and talkative body, fighting for the rights of corporations, but "one supreme controlling authority, entrusted with larger powers than those possessed hitherto." The universities have been much considered by the Commissioners, and their graduates will be exempted from all the examinations of the divisional board but the final one, and this at a small fee.

A deputation of members of the British Medical Association, and others, waited on Lord Carlingford and Mr. Mundella in November, to urge on the Government the promotion of legislation on the lines of the recommendations of the Royal Commission. Dr. Waters, of Chester, gave a history of the arguments and demands for reform, and of the efforts of successive Governments; and Dr. Glover spoke from the point of view of a Scotch graduate and the holder of a Scotch diploma. Mr. Wheelhouse, of Leeds, testified to the fact that those who are rejected in one division of the kingdom often quickly succeed in another. Both Lord Carlingford and the Vice-President listened attentively to the deputation, and promised that the subject should have their attention.

In Parliament, excepting answers to questions of more or less medical interest, there has been little to record in a session barren beyond precedent. The chief redeeming fact about the work of Parliament is that the House of Commons has awoke to the absurdity of its own Rules of Procedure, which have served lately so to hinder legislation as to bring the Legislature itself into disrespect.

Medico-Legal Cases.

The year 1882 has not afforded many cases of very exceptional interest in the domain of medical jurisprudence. The humiliating circumstance of the conviction and execution for murder of a member of the medical profession will, however, cause the past year to be held in bitter remembrance. The circumstances of Lamson's crime need not be recapitulated, how for the sake of gain he administered acconitia to his brother-in-law in a gelatine capsule, and how the crime was clearly brought home to him by the aid of chemical and physiological tests. The satisfactory way in which the alkaloid was detected by Dr. Stevenson and Dr. Dupré will effectually tend to deter miscreants of a similar type to Lamson from using this lethal agent for the future. Owing to the public panic caused by this case, the Home Secretary issued circulars to various bodies asking for their opinion as to the necessity or otherwise of altering the law which regulates the sales of poisons. Committees were appointed by the different medical colleges, and we doubt not that much information was furnished to the Home Secretary; but as yet no steps have been taken to alter the law. Quite recently a woman named Taylor was convicted of murdering an old woman by the administration of sugar of lead. The circumstances were so lately given in our columns as to make a repetition of them unnecessary. On the last day of 1881 a curious death-bed confession was made by a man named Brooks, in Staffordshire. It appears that Brooks, a somewhat eccentric man, attempted to castrate himself on December 4th, 1879, and, in explanation, he falsely alleged that he had

been mutilated by four men who attacked him. The result of this statement was that two men (Johnson and Clowes) were sentenced to ten years' penal servitude. On February 13th, 1881, Brooks again attempted to castrate himself, and again made a false statement that his injuries had been inflicted by others. He died from the effects of heart disease on December 31st, 1881, and his death-bed confession led to the liberation of the men who had been wrongly convicted. The conviction and execution of Guiteau for the murder of President Garfield must be regarded as just in spite of the preposterous attempt to prove the murderer insane. That Guiteau was on the borderland of insanity there can be little doubt, but of the expediency of his execution there can be little doubt also. In the spring public indignation was aroused by an attempt on the life of the Queen by a man named Maclean. Maclean was arraigned for high treason, and was acquitted on the ground of insanity. Maclean had been in a lunatic asylum, and there never was from the first any doubt as to his unsoundness of mind. It was a clear blunder to go through the farce of a trial, and thus give a notoriety to the case, which would prove an incentive to lunatics of a similar class to imitate Maclean's action.

The Brighton Corporation and THE LANCET.

Early in the year we had occasion to question the perfect state of the sewerage of Brighton—a course which gave great offence to the Town Council, who commenced an action for libel against *THE LANCET*. They, however, directed Sir J. Bazalgette to report on the sewerage system, and Dr. Richardson on the sanitary condition of the town. These reports agreed in the main with our strictures on the imperfect system of drainage. The Corporation, after the publication of Dr. Richardson's report, with commendable discretion, retired from the contest. Thus the liberty of the press was vindicated. If we cannot discuss (which we do every week) the sewerage or insanitary state of a town, one great function of *THE LANCET* will be paralyzed. Our aim and mission are to diffuse scientific knowledge throughout the world, and to reform local abuses. The amount of good accomplished by the Brighton agitation is simply incalculable. Every healthy resort throughout the kingdom had its drainage overhauled and its pestilential spots purified. Perhaps the authorities expected a visit from one of our Commissioners. But as it is we congratulate ourselves and the Town Councils who have "put their houses in order."

Public Health Questions.

The year which is now passing away has, on the whole, been a healthy one at home. In England and Wales the general mortality, so far as it can be ascertained at this date, has been decidedly below the average. A comparatively mild winter led, in the first quarter of the year, to one of the lowest death-rates which has been recorded since civil registration was established in 1837. In the metropolis itself, however, an exceptional fatality from pulmonary affections amongst persons over sixty years of age was brought about by the density of the prevailing fogs. Throughout the year the prevalence of small-pox has been diminishing. In the metropolis, indeed, the small-pox death-rate is decidedly below the average for the ten preceding years, but several severe outbreaks have occurred in the provinces. It is a matter of experience that a London small-pox epidemic is always followed by an extension of the disease to some at least of the other large towns and cities, and the only peculiarity of the last epidemic is that this exten-

sion was longer in showing itself than usual. Amongst the English provincial towns that have most suffered are Bolton, Gateshead, Hull, Leeds, Lincoln, Newcastle-upon-Tyne, Nottingham, Rochdale, and Wednesbury. The mortality from the several continued fevers has also been below the average. In some parts of the kingdom isolated outbreaks have, however, occurred, and of these the epidemic of enteric fever at Bangor has been by far the most extensive. During the four months June to September over 550 cases of this disease occurred in Bangor and its immediate neighborhood, the outbreak being one of the most severe which has been recorded in this country within recent years. A searching inquiry was made into the circumstances of the epidemic by Dr. Fred. W. Barry, the newly appointed Medical Inspector to the Local Government Board, and it was proved that the outbreak had in the first instance been brought about by the contamination of the water-service into which the specifically poisoned excreta of an isolated case had been conveyed by faulty means of drainage, and that its extension was in the main the result of an ill-ventilated system of sewers which facilitated the entrance of the then fever poisoned drain air into dwellings. The long continuance of the epidemic was also favored by the failure of the sanitary authority at once to act on the recommendations of Dr. Barry and of their own officer of health. The occurrence of small outbreaks of typhus fever in several large centres of population, and especially in Liverpool, London, and Sunderland, naturally led to the fear that, with the colder weather and the resulting overcrowding in the ill-constructed and ill-ventilated tenements of the lower classes, some epidemic prevalence of that disease might be anticipated. Although, however, more than the usual interval between epidemic prevalences of this disease has elapsed since the last typhus visitation, we are fortunately still without any indication of its further spread. Scarlet fever has, like the continued fevers, been distinctly less prevalent than usual, but in several parts of the kingdom local outbreaks of considerable magnitude and severity have occurred. Amongst the larger towns Accrington, Gloucester, Merthyr Tydfil, South Shields, Oxford, Nottingham, and Hull may be named as having specially suffered; the outbreak in Hull being a continuance of an epidemic which in 1881 caused as many as 682 deaths. The disease has also been fatally and persistently prevalent in several smaller places, such as Worksop, and also at Upwell, a village near Wisbeach. Diphtheria has throughout the year caused an excessive mortality, the excess increasing as the year has progressed; and in some places, such as Folkestone, Taunton, Sutton-in-Ashfield, Lynn, and Whitstable, there have been marked epidemic outbursts of the disease. We are fortunately still ignorant of the conditions essential to the development and, to some extent, to the spread of this affection, and with a view of acquiring further information as to its etiology, both the Local Government Board and the British Medical Association have instituted a series of detailed inquiries, the results of which may, it is hoped, hereafter give some indication as to how the diphtheria mortality may be lessened. Both whooping-cough and measles have prevailed to an unusual extent, and some of the measles epidemics have been very fatal. So long, however, as attacks of these diseases are regarded by the ignorant as necessary to the period of childhood, so long must they lead to a large number of preventable deaths. The periodic prevalence of autumnal diarrhoea has been less marked this year than usual, and it is evident that a comparatively cool autumn has in part conduced to this result. But

it is equally clear that temperature alone does not regulate the extent of diarrhoea mortality amongst infants. The available information as to the causation of this disease is as yet singularly imperfect, and we can only await the results of the exhaustive inquiry which, now for three successive autumns, has been undertaken by Dr. Ballard, with a view of clearing up at least some of the more difficult sanitary problems connected with this subject. Leicester, Preston, Hull, Gateshead, and York have, as usual, suffered exceptionally from infantile diarrhoea.

During the year the subject of the isolation of the several infectious fevers has received a large amount of attention, and three important reports have been issued on the subject. The first was Dr. Thorne Thorne's exhaustive report on the Use and Influence of Hospitals for Infectious Diseases throughout the country generally; a report which embodies all the information available on the subject so far as the requirements of sanitary authorities are concerned. The second was Mr. W. H. Power's report on the influence of the Fulham Small-pox Hospital, which went to show, in the most convincing manner, that the aggregation of a large number of small-pox patients in a populous centre was attended with a spread of the disease amongst the surrounding inhabitants. The report was one of the most complete that has ever been issued by any sanitary department. It proved that the diffusion of the small-pox contagion had operated over a wide area; that it had come into operation every time the hospital had been used for the reception of acute small-pox cases; and that, owing to the uniformity of its incidence upon all the surrounding population, quite irrespective of the existence of roads or other channels of human intercourse, the diffusion must necessarily have been communicated through the atmosphere. The circumstances elicited as the result of this investigation led to the appointment of a Royal Commission to inquire into all the circumstances affecting the isolation of infectious diseases within the metropolis, and the report of that Commission formed the third contribution to this important subject. The Commissioners arrived at the conclusion that the metropolitan small-pox hospitals had operated injuriously upon the neighborhoods in which they are situated; and although not assenting in full to Mr. Power's contention that the mischief was brought about by aerial diffusion, yet they would appear to have been largely influenced by this view in so far as their recommendations are concerned. We have so recently commented on this report that we would now only add a hope that legislation will speedily give effect to the conclusions which have been urged upon the Government by the Commission. The deaths by erysipelas following vaccination in Norwich were considered of sufficient importance to demand public inquiry by the Local Government Board, who, in the first instance, appointed Dr. Airy to investigate the circumstances attending the fatality. Subsequently Mr. Henley was associated with Dr. Airy in the inquiry. The report was so unsatisfactory that Dr. Buchanan deemed it necessary to append a memorandum showing that the conclusions arrived at by the inspectors were not borne out by the evidence, and that important considerations which might have led to the elucidation of the cause of the erysipelas had been overlooked.

The Parliamentary session has been very barren in sanitary legislation, and only two statutes call for any notice. One extended the Public Health Act so as to enable sanitary authorities to make by-laws regulating fruit pickers and their lodgings; the other amended the Artisans' and Laborers' Dwellings Act, and provided means, amongst

other things, for the purchase of houses, the demolition of which was necessary for the opening up of alleys, etc. Two other subjects, however, deserve notice in this connection. During the year the Local Government Board completed their series of model by-laws by the issue of several sets of clauses for the regulation of noxious trades; and the Education Department of the Privy Council in their New Code of 6th March, 1882, made provision for the issue of grants in the case of schools which, without being closed, may suffer from a diminished attendance owing to the prevalence of infectious disease, and also for requiring school managers to comply with the notices of sanitary authorities as to the closing of schools or the exclusion of scholars under similar circumstances.

Europe has fortunately escaped from the importation of any Eastern epidemic disease. Plague has, however, prevailed to some extent in Persian Kurdistan, the disease reappearing after an apparent cessation of several years. The rumors as to the dangers which we run by the importation of cholera through the Mediterranean have been unusually rife, and the presence of that disease in an epidemic form, both in India and in some of the islands bordering on the China Sea, led to an attempt to hinder traffic through the Suez Canal at a critical moment of the recent Egyptian campaign. England, however, distinctly refused to subject herself to the regulations which the Egyptian Board sought to impose, and the result has fully justified the course she took. It is to be hoped, indeed, that before long some final settlement on a rational basis will be made as to the constant disputes arising with reference to the subject of quarantine, as this antiquated process is understood in Egypt and in some other countries. Following on the Mecca pilgrimage cholera broke out in the Hedjaz and other localities affected by the annual visit to the holy city. At Jeddah the disease still prevailed in the middle of last month, but so far as Europe is concerned, all danger may now be regarded as having passed.

Miscellaneous.

A very notable event during the past year has been the opening of the Royal Courts of Justice, and in a future number we shall give a report on the sanitary aspects of the new building. The building, although praiseworthy, is by no means above criticism, and it is to be hoped that in the future when Government offices have to be erected some of the suggestions offered by our Commissioner will be acted upon by the Government of the day.

A very laudable attempt to improve the sanitary condition of ships was made by the Directors of the Orient line in the construction of the steamship *Austral*, undoubtedly the most magnificent vessel of its class. This ship's career has been most unfortunate, for she was capsized a few weeks since in Sydney Harbor, owing to the carelessness of those in charge during coaling, and although it is hoped that she may be floated again, one cannot but have misgivings that the difficulties of such a work may prove insurmountable.

The Parkes Museum has been incorporated during the past year, and has been removed from University College to new premises in Margaret-street. It will be opened early in 1883, and we can only wish it a long career of useful activity.

Obituary.

The obituary of every successive year seems sadder than the previous ones, though in the case of the present year it includes the names of many whose age and honors were fully ripe. A few selections from our own death record will show what

figures have disappeared:—John Flint South, F.R.C.S. Eng.; Sir Robert Christison, Bart.; Charles Robert Darwin; Professor Schwann, of Liege; Dr. George Budd, F.R.S.; Sir John Rose Cormack, of Paris; Sir Edwards Burrows Sinclair, of Dublin; T. B. Peacock, M.D.; Professor James R. Wood, of New York; Professor Spence, of Edinburgh; Professor Andrew Buchanan, of Glasgow; Dr. Arthur G. Reid, of Hankow; Dr. Charles Morehead, of Bombay; Sir James Alderson, M.D. Oxon.; Mr. J. T. Clover; Dr. Edward Peele, of Dublin; Mr. George Critchett; Bhola Nath Bose, M.D. Lond., Bengal; Professor George Gulliver, F.R.S.; Professor Henry Draper, of New York; Professor William Pirrie, of Aberdeen; Dr. Edwards Crisp; Sir Thomas Watson, F.R.S.; Dr. Edward J. Reynolds, the oldest physician in Boston, who graduated at Harvard fourteen years before Sir Thomas Watson graduated at Cambridge; Deputy Surgeon-General Pearse, late and most valued Chief Officer in the Vaccination Department of the North-West Provinces of India. We should want all the columns of the "*Annus Medicus*" to record the work represented by these names and the names of practitioners in the more laborious fields of private practice, some of them dying, like Lycidas, in their prime, most of them at their post, and not a few filling offices of public trust.

Conclusion.

Now we leave 1882, wishing our readers all happiness in the coming year and inviting their co-operation in perfecting the art and science of medicine, with which the well-being of mankind is seen to be more and more inseparably connected.

Editorial.

THE PROSPECTS OF MEDICINE IN THE NEW YEAR.

In entering on a new year it is proper to encourage the feeling of hopefulness and expectation. The man who expects most is, after all, he who generally receives most. The history of medicine in recent years justifies the cultivation of a more sanguine mood than is generally attributed to medical men. Doctors are by no means a melancholy set of men. The reason is that they see infinitely more of recovery and convalescence in their experience of disease than of the opposite, and that while receiving plenty of abuse, they receive more praise and gratitude. There have been few more popular physicians than Mead, and few who saw more of disease; yet Dr. Johnson said of Mead, "He lived more in the broad sunshine of life than almost any man." This is the true mood for a physician, and if a physician in Mead's time could manage to live in the sunshine, *a fortiori* it should be practicable now. With all the admitted limitations of medical art, it is an infinite relief to the suffering portion of the community to receive the visit of a medical man who devotes his life to the removal and mitigation of disease, and who does not readily admit any case to be beyond the reach of some benefit. As in a storm many a captain carries his ship safely through who perseveres in a cheerful and hopeful contest with the waves,

se, in extreme circumstances of disease, the physician who is hopeful and has resources, and who has therefore a power of exciting hope in his patient, will often bring the patient through, or extend his life, where a less hopeful or resourceful practitioner would fail. Mead's name reminds us of the strides of medicine. He was honorably associated with the introduction of inoculation for small-pox. Since then this great plague has been brought well within the control of enlightened States by an operation which suggests the hope of similar triumphs over other diseases. Objectors will retort that States are still afflicted with huge epidemics even of small-pox, and that other fatal diseases still defy medical art—cancer, hydrophobia, consumption, and the various forms of degeneration which neither Bright nor Addison has shown us how to arrest. There is too much truth in this retort to be pleasant. But it is not so true as to damp the ardor of the physician. The great cause of the prevalence of small-pox, for example, is not the imperfection of medical art, but the imperfect intelligence of the people, disabling them for a perfect appreciation of vaccination and revaccination. In the great field of septic diseases, medicine, or rather surgery, has lately made enormous advances. As in the case of small-pox, so, in a less striking way, medicine has pointed out how many other epidemic diseases may be curtailed, but mistaken notions of liberty, or imperfect states of popular intelligence, which it is the beneficent purpose of medicine to remove by the diffusion of medical knowledge, still stand in the way. As regards the case of consumption, of late years its curability, or the chance of beneficially influencing a natural tendency to self-limitation, as Dr. Flint happily calls it, has been fully admitted, and the recent discovery of Koch—by the way, originally a country practitioner—justifies a hope that further means may yet be found of preventing the extension of this disease in individual cases, or from one person to another. The various forms of degeneration—Bright's disease, Addison's disease, atheroma, and myxœdema, etc.—are no doubt still great *opprobria* of the medical art, instances of disease in which pathology has far outstripped therapeutics. But does anyone doubt that a man affected with any one of these diseases will be greatly the better for following the advice of a sage and kindly physician? This is one of the most useful departments of medical service and labor. The extension of time taken to effect a given amount of degeneration, and the circumstances influencing the progress, or, if we may so say, the *pace* of degenerations, is one of the most interesting fields for further work and investigation. Meantime it is certain that medicine can do much to retard the progress and to abate the *pace* of such diseases. So that when a great life is visibly affected with such changes, there is still good hope that by medical wisdom it may be lengthened out for years to add to the lustre of the State, and pos-

sibly to the peace and happiness of the world. We encourage our readers, therefore, to take an ever increasingly hopeful and cheerful view of the progress of medicine and of their power to affect beneficially the progress of disease. There were never so many workers in earnest to discover the secrets of disease as now, and they were never backed by a more intelligent and well-educated body of practitioners.

We have a good hope that the year will witness some legislative attempt to increase the efficiency of medical education and to abate the worry of multiplied medical examinations; to raise the minimum standard of medical education, and, in raising that, to raise the higher standards of it. The Corporations of the profession which represent its real life and glory will survive; others may disappear. Be this as it may, we enter on the duties of another year with the conviction that British medicine and surgery will hold their place in the great competition of the world, and that this country will never want men to stand worthily in the succession of Harvey and Sydenham and Jenner and Hunter.

THE PRACTICAL VALUE OF THE TUBERCLE BACILLUS.

THE practice of medicine is based upon pathology; but the two departments of medical science rarely correspond in their development. Each is at once ahead of and behind the other. There is much that is well established in practice of which pathology has not yet supplied the explanation. There is still more in pathology which has as yet no practical application. But as medicine is an art as well as a science, the application of each new scientific fact is eagerly sought for, and the more earnestly when the fact is one which relates to a disease at once frequent and formidable. At the present time the question is being asked on all sides, What is the practical value of the discovery of the organisms which seem to be so intimately connected with the formation and growth of tubercle? A decisive answer will probably not be long deferred, for the question is engaging the attention of many who are well qualified to search for a reply. Already in Germany and Switzerland answers have been attempted, but between them there is not perfect concord.

In the *Berlin. Klinische Wochenschrift* (1882, No. 45), Balmer and Frænzel have given an account of the examination of the sputa in one hundred and twenty cases of phthisis. They found the bacillus in all, while in the expectoration from cases of ordinary bronchitis the search for it has always been in vain. They have gone further, and endeavored to ascertain what prognostic indications can be deduced from the presence, abundance, and character of the organisms. They believe that the number and degree of development of these are of considerable prognostic value; and that the prognosis is bad whenever the bacilli are numerous

and well developed. In the most acute cases the organisms were exceedingly abundant. The more rapid the process of lung destruction the larger is their number, and it is greatest towards the end of the disease. The distinctive and developmental character of the organisms presents considerable variation in different cases. Sometimes they were small and presented no trace of spores, and in this case they were always few in number, and the disease was either arrested or making very slow progress. In the rapid cases, with fever, night sweats, etc., the organisms were not only numerous, but large, well developed, and spore-bearing. In post-mortem examinations, a marked difference was found between the number of bacilli in the walls of the cavities and in their contents. They were scanty in the former when they were most abundant in the latter. Hence it is assumed that the sputum is a more suitable field for the development of the organisms than the living pulmonary tissue. The difference can scarcely be explained by the presence of oxygen in the contents of the cavities, since the bacilli were found in great numbers in the pus within a knee-joint, the seat of tubercular inflammation, perfectly protected from the presence of air.

Professor D'Espine, of Geneva, has carried out a similar investigation (*Revue Médicale de la Suisse Romande*, Dec., 1882), but can only partially confirm the conclusions of the German pathologists. According to him, Koch's discovery is of the greatest diagnostic value, but as an element in prognosis the bacillus is almost worthless. He has found the organism in the expectoration of twenty cases which were regarded on other grounds as tubercular; and they were absent in five cases which were diagnosed as bronchitis with emphysema; although in several of these there was a chronic induration on the apex of the lung, with dilatation of the bronchi. One of these patients, it is incidentally noted, had been for a year in a bed adjacent to that occupied by a tubercular patient, and certainly ought to have presented the bacilli if these come accidentally from the atmosphere. Of the twenty positive cases, in seven the organisms were present in large quantity; but in five of these there was no fever, and the disease had a very chronic course; one of them, indeed, was in a condition of arrest and in good health; the two others had hectic fever and extensive cavities. Five or six were suffering from laryngeal ulceration, and it is possible that from these ulcers most of the bacilli came. In thirteen cases the bacilli were scanty, and in some were arranged in groups. In some instances only two or three were found, after a series of preparations had been examined. One of these cases presented high pyrexia, and another with an enormous cavity died a few days afterwards. Hence the Professor concludes that the assertions of Balmer and Fraentzel relative to the prognostic value of the number of bacilli in the sputum are erroneous. The same conclusion is reached by

D'Espine regarding the significance of the degree of development of the bacilli. In some cases very distinct segmentation was seen—sometimes five or six cells in juxtaposition. Sometimes there were small round shining points, which may have been spores. He thinks, however, that it is better to speak of unicellular bacilli and multicellular bacilli in process of segmentation. These two forms were met with indifferently in chronic cases which caused no anxiety, and also in cases which were very near their termination. Hence he believes that it is an illusion to regard the developmental character of the bacilli as affording any prognostic indications. In a case of acute miliary tuberculosis the scanty expectoration showed no evidence of bacilli, and hence in this variety, in which diagnostic help is so much needed, it seems unlikely to come from this source. In conclusion, D'Espine insists on the necessity of numerous and repeated examinations on different days, before the absence of the bacilli is regarded as certain.

THE PATHOLOGY OF INTERSTITIAL NEPHRITIS.

A DISTINGUISHED German pathologist, Dr. Aufrecht, has for some time maintained the opinion that all forms of diffuse nephritis begin in a similar manner; and that in all, even the interstitial variety, the inflammatory process is essentially "parenchymatous," and starts from the epithelium of the glomeruli and urinary tubules. In support of this view, he published some time ago a series of experiments on temporary ligature of the ureter. He found that the first effect was to be observed in the epithelium, which became granular and cloudy, and gave rise to fibrinous tubercasts. During the first few days the interstitial tissue of the kidney was perfectly normal, and only on the fourth day was there a dilatation of the Malpighian capsule, whilst the cellular elements between the tubules presented a swelling of their nuclei. Subsequently the walls of the vessels became increased in thickness, chiefly in consequence of a swelling of the adventitial and muscular layers. At the same time further changes could be perceived in the epithelium of the urinary tubules. The epithelial elements became transformed into small pale cells with a distinctly visible nucleus. They did not, however, appear to perish, although the interstitial tissue subsequently increased in bulk in consequence of the swelling of the nuclei, and cell multiplication, with a corresponding narrowing of the lumen of the tubules. Thus by ligature of the ureter a morbid process was set up, ultimately interstitial, but beginning distinctly in the intra-tubular epithelium. Reigert has urged that the interstitial changes are secondary to destruction of the tubular epithelium; but in these cases the epithelium persisted, although in an altered condition, while the interstitial changes were being established.

Straus and Germont, in France, have recently

also studied the effect of ligature of the ureters in the guinea-pig. They did not, however, find any interstitial changes, and are inclined to attribute the absence of these to the strict antiseptic precautions observed in their experiments. Where such precautions are not observed, micro-organisms may find entrance; and through these, directly or indirectly, the interstitial process may be produced. This objection cannot, however, be allowed much weight. It is a gratuitous assumption to suppose that micro-organisms are capable of producing such effects and no others, and quite illegitimate as a means of explaining a discrepancy between the results obtained by two sets of experimenters. The French observers have, moreover, confirmed Aufrecht's observations on the mode of origin of tube-casts by the production from the epithelium of separate clear spherules, and their union within the tubules. They have also confirmed the thickening of the adventitia and muscular coat of the smaller vessels, and the thickening of the membranæ propria.

But the evidence which Aufrecht has adduced to show that in one form of diffuse nephritis the morbid process commences within the tubules cannot be regarded as necessarily applicable to all forms of renal inflammation. Experimental evidence is needed regarding the process in other forms of nephritis, which proceed to a greater degree of structural change than that which follows the transient ligature of the ureter. Some further evidence Aufrecht is now in a position to supply. In a communication to the *Centralblatt für die Med. Wissenschaften*, in which he reviews the facts above alluded to, he states that by the subcutaneous injection of small quantities of cantharidin, suspended in oil, he has succeeded in producing almost all forms of nephritis—the so-called acute parenchymatous form, the diffuse parenchymatous-interstitial form, and even the contracted kidney, with granular surface and marked depressions. All these varieties of nephritis were produced by the same method, the only difference being that to give rise to the contracted kidney the injections of cantharidin had to be frequent. As a rule, the largest and strongest animals required the greatest number of injections; but in one case, a single injection in a rabbit which had just completed a period of lactation set up an acute parenchymatous nephritis, which was fatal. This interesting pharmacological fact has afforded Aufrecht the opportunity of studying the evolution of these morbid states. In the earliest stage the glomerular epithelium was found to present considerable swelling, and was separated from the wall of the capsule. The tubular epithelium was cloudy, swollen, and contained clear refracting bodies, which, becoming free, produced tube-casts, just as in the case of ligature of the ureters. Subsequently the epithelium of the glomeruli became swollen, as well as the nuclei of their vessels. That these changes are really inflammatory is shown by

the appearances presented in a further stage, when it deserves the name of "parenchymatous-interstitial nephritis." The changes in the epithelium of the convoluted tubules were manifested in a still more considerable degree. The cells were small, flat, and pale, but were nowhere absent, though some of the glomerular epithelium had disappeared. The vessels contained little blood, as if the swelling of the nuclei had prevented the passage of the blood into them. The interstitial tissue was, however, increased in area in all parts, in consequence of swelling of the nuclei, especially between the convoluted tubules and in the neighborhood of the glomeruli. There was no indication of an excess in the number of cellular elements in the interstitial tissue, or of any migration from the vessels. From these facts Aufrecht concludes that the changes must be ascribed to a specific affinity of the cantharidin to the epithelium, exciting in the latter some chemical process, which ultimately influences also the interstitial tissue in the way described.

Granular degeneration of the kidney, in its most perfect form, was produced by twenty-five injections of cantharidin (.0025 gramme), extending over four months. The microscopical appearance of the organ was similar to that of the same condition in man. By the contraction of the interstitial tissue the glomeruli and renal tubules were much narrowed. The former were denuded of their epithelium, and their structural elements could scarcely be recognized. The epithelium of the renal tubules was shrunken, and the bodies of the cells had a protoplasmic aspect. Here and there the lumen of the tubules was occupied by casts. These results Aufrecht holds to be evidence of the etiological and pathogenetic relation between parenchymatous nephritis and the contracted kidney, and that even in the latter the morbid process begins within the tubules.

IN PERILS BY HYSTERICAL DELUSIONS.

DRIVERS perils beset the professional life of a medical practitioner, but there are few, if any, so difficult to escape as the hot and scathing breath of scandal, through the half hysterical and half vicious calumnies of women. It is cause for sincere congratulation and thankfulness that the proportion of instances in which this perpetual and universal danger to which members of our profession are exposed is signaled by a catastrophe, is so small as to be almost insignificant. When, however, a scandal does occur, it is notorious, and the effects it produces are calamitous in a degree which seems to be enhanced by the fact that medical men habitually incur the direst risks, and, except in the rarest instances, with impunity. Nevertheless, it cannot be disguised that the practitioner is always very much, and in a most important sense, at the mercy of his female patients. Even though the wholesome and expedient precau-

tion of never seeing a woman alone be rigorously adopted, it is impossible to assure the character against aspersions which do not need to be clearly defined in order to render them damaging. It is only too true that whatever may be the ending of a slanderous assault on the reputation of a medical man he cannot fail to be the sufferer, unless, indeed, the most fortuitous circumstances should combine to clear his character. We have at this moment in recollection a case in which a charge was brought with every appearance of plausibility by a young woman against a hospital physician; and in such a way that, but for the spirited friendliness of his colleagues, he must have fallen a victim to the calumny, when, by the most wonderful good fortune, the true nature of the imputation was suddenly and unexpectedly made apparent by the patient developing an attack of acute mania within a few hours of the narration of her perfectly coherent and precise story. It is seldom indeed that a medical man so placed has his character so promptly and triumphantly vindicated.

As a matter of fact, the presumption is always against the truth of any assertion made by a female patient maligning her "doctor." It is in the highest degree improbable that any man who has passed through the training indispensable for a medical qualification should—unless he be insane—so far forget his position, or be affected in such a manner, as to commit himself. Nothing short of the most conclusive evidence ought to suffice for the proof of guilt in the case of a qualified man so situated as to be the subject of an imputation. The whole conditions of a medical or surgical procedure are incongruous with the bare idea of offence. We do not hesitate to declare that, except on the clearest and most incontrovertible evidence, we would not believe it possible that a brother so placed should offend. On the other hand, nothing is more likely—we had almost said natural, but let us rather say morbidly probable—than that a woman affected with any of several maladies which call for surgical interference, should develop one of those prurient states of mind which are, indeed, *symptomatic* of the diseases to which we allude, and become the victim of a characteristic delusion of which the medical man in attendance is readily made the primary figure. Knowing these facts, patent as they must be to every member of the profession, and recognizing the besetting peril of practice among women, it is inexplicable on the one hand, that medical men should ever neglect the precaution of having a trustworthy female witness present during the whole of every necessary examination or operative proceeding; and on the other hand, that any member of the profession should for one moment cherish an evil thought of a brother practitioner, or entertain a suspicion of his integrity while the imputation cast on his honor is as yet unproved. The danger of a baseless charge is so great that no man should despise or underrate it; and the improbability of

actual wrong-doing is so high that no reasonable person should entertain a belief in the fact of its occurrence so long as there remains room to doubt it. We cannot too strongly insist on the duty of protecting ourselves, and defending others from the least breath of scandal. No medical man is justified in trusting to the honor of his patient. Setting aside the possibility of a malignant purpose, it should be distinctly borne in mind that no woman who suffers from a uterine or ovarian trouble of any kind, or who is the victim of hysteria or mental disease of whatever class or description, is safe from the sudden development of a psychological reflex that may easily take the form of a personal delusion which shall place her medical attendant in an equivocal position. This contingency, which need not involve any overt or recognizable disturbance of the intellectual faculties as a whole—and which may therefore lead to the fabrication of a perfectly coherent and circumstantial story—does not appear to be generally understood and anticipated. The present is not—unhappily—an inopportune moment to remind the profession generally of a fact which is continually present to the mind of the alienist, and of which lunacy practice affords frequent and conspicuous examples. Looking to the facts of the case, it is, indeed, surprising that practitioners who are almost daily placed in a position of extreme delicacy enjoy a large measure of immunity from the consequences of a danger which perpetually overshadows them. Let him that thinketh he standeth in no peril of this description take heed lest he fall a victim to its toils.

THE MENTAL ELEMENT IN TREATMENT.

At a time when pathology is doing so much to remove the study of medicine from the empirical to the exact, and when observation of the therapeutic effect of various drugs bids fair to largely increase our knowledge of specific remedies, there seems at first sight little reason why the medical mind should even for a moment be drawn aside from the objective to the subjective view of disease, as the tendency of advancing research is constantly to diminish the number of maladies in which an important part is played by conditions out of reach alike of the scalpel and the microscope. The time is not so long gone by when, even within the profession itself, many familiar diseases were supposed to depend upon spiritual, perhaps extra-terrestrial, causes, the operation of which was scarcely a legitimate object of inquiry. Up till the present moment, indeed, large numbers of the people look upon disease generally as a direct infliction of Providence, while many more believe special outbreaks to be the consequence of a more than usually perverse departure from the paths of rectitude. A certain phase of this belief is favored by the profession, but our constant effort is to ascertain the nature of those laws whose silent but certain rule we can break only at our peril. There

are departures from health in abundance which, whether serious or slight, we cannot satisfactorily explain or demonstrate, and a very little of superstitious awe is required to see in these the direct interposition of an offended Spirit.

We do not need to express the very slight hold which all such feelings have upon the medical profession, but it may be useful to bear in mind the large share which superstition and sentiment take in shaping the lives of many of our patients. There are conditions coming frequently within our ken as physicians which we might with much probability of truth view simply as diseases of sentiment or will, and these in people whose business and general mental capacity cannot be suspected. Trivial twists of mind may or may not depend in all cases upon a physical change in the brain, but there can be no doubt that we have many apparently functional disorders of mind as well as of body to deal with. Even though the really important disease from which our patient suffers be gross and easily named, there may as a result ensue a condition of mind which the thoughtful physician will recognize and appreciate, whether as a help or hindrance in his work. The dictum that a favorite drug is useful for a particular disease may not unfrequently be found fallacious if the mental condition of the patient is overlooked, and one chief difference between the thoughtful, intelligent, and successful physician, and another who is neither consists in the attention which the first, perhaps unconsciously, devotes to this factor in his case. We are too much in the habit of treating our patients simply as machines which have got out of order, and inasmuch as their feelings are always deeply concerned in bodily ailments, we would do well, so far as we can, favorably to affect them in that quarter. Sympathy is a powerful drug in the hands of a skilful administrator, and we should no more neglect its use than we would other weapons of our armamentarium. Everyone practically acquainted with what is called the natural history of disease knows well that a particular malady affecting a patient of sanguine temperament may be looked upon with more composure than, all other things being equal, would be the case were the sufferer of phlegmatic constitution. In the one case we can rely on a resiliency which will fail us at the critical moment in the other; and many recoveries take place which upset our prognosis, because apparently the object of our care "will not kill." Men who cultivate a hopeful demeanor in the sick room will more readily elicit this helpful buoyant spirit than others who are constitutionally grave and desponding, and men of the latter character may unwittingly hinder the recovery they are so anxious to promote. Physicians prone to gravity in all things are heavily handicapped in their work, but a steady recognition of the fact may lessen its ill effects, while, by a sort of compensatory law, they have often the happiness to inspire a

confidence which may be equally useful to the patient.

Though the therapeutic effects of hope and confidence are not detailed in our text-books, they are enough often to turn the scale in favor of recovery; and yet they are but two of the many mental medicines which a judicious physician or surgeon may exercise in the management of disease. There is much solidity in the faith placed by families in their ordinary attendant on the ground that he knows the constitution of each of its members, and when this is not the case his intimate acquaintance has not been turned to good account. In no respect has the family physician such an advantage over the consultant as in this, and obviously it is an advantage which upon fit occasions can be shared and utilized. A full recognition of the value rightly attaching to the mental treatment of physical ailments will improve the usefulness of the physician, give him a higher place in the affection of his patients, and materially assist in promoting their return to health when suffering from very various diseases, functional or organic.

Reviews and Notices of Books.

Quain's Elements of Anatomy. Edited by Dr. ALLEN THOMSON and Professors SCHAEFER and THANE. Ninth Edition. London: Longmans, Green & Co. 1882.

THE name of Quain has long disappeared from the list of editors of this work, and now that of Sharpey is also missing. The late Professor Sharpey had been so long and honorably associated with the production of its successive editions; his writing and supervision conferring on the chapters on the general anatomy of the tissues and the anatomy of the viscera their especial charm of style, their marvellous accuracy, and progressive development in accordance with whatever has been new and at the same time true in modern research, that it is hard to realize the issue of an edition without his name on the title-page. But, alas! he has passed from amongst us, and we are reminded by a simple preface of the great debt which anatomical and physiological science in England owes to his writings and example: "This ninth edition of 'Quain's Elements of Anatomy' is dedicated to the memory of William Sharpey, M.D., LL.D., F.R.S., formerly Professor of Anatomy and Physiology in University College, London, and during thirty-five years one of the editors of the work." The chief responsibility of the revision has therefore devolved on Dr. Allen Thomson, who now for the third time appears as editor, in association with Professor Schäfer, who was responsible for most of the histological portion of the preceding edition, and Professor Thane, to whom has now been allotted that part of the subject which deals more especially with descriptive anatomy. We congratulate Professor Thane on his succession to so honorable a distinction, and we consider the choice an admirable one, having regard both to Professor Thane's extensive and accurate anatomical knowledge, and to the fact that to his predecessors in the Chair of Anatomy at University College the work itself owes its origin, its special fea-

tures, and many of its most marked improvements.

The first volume of the new edition contains the descriptive anatomy of the bones, joints, muscles, vessels and nerves, and a special chapter on superficial and topographical anatomy, whilst the second volume is devoted to general histology, the anatomy of the viscera, and embryology. The chief alteration in the text of the descriptive anatomy is in the chapter on the bones of the head, to which a short but very clear account of the methods of modern craniometry, with examples of the varieties of the skull in some typical races, has been added. As minor changes we find the position of the liver in the living subject described according to His, the classification of the cranial nerves according to Soemmering, and the divisions of the mediastinum mainly in accordance with the views of Struthers. The superior division of the mediastinum is introduced, and its boundaries and contents are for the first time laid down in a textbook. We much prefer the divisions of the pleural interspace which were suggested by Professor Wood in his article on "The Arch of the Aorta," in the *Journal of Anatomy and Physiology* for 1868, to those of either Professor Struthers or the editor, and it is in that article that the great importance of a more accurate division is first referred to, and the "superior mediastinum" as a distinct region named and defined. The laborious and careful investigations of Wood on the true position of the aorta and the thoracic contents, which have only been introduced into the last two editions of "Quain's Anatomy," demand far more notice than the general description given by Struthers. Even the very term "superior mediastinum" is used by Wood. The sections on the bones, joints, muscles and nerves show marks of careful revision, and those on the vessels are now much improved by colored drawings. We could wish that some of the illustrations of the bones, especially those of the skull, and even of the more important nerves, had been replaced by new and larger woodcuts, for when the details are so very numerous, any representation which is overcrowded with reference-numbers is of but little value to the student. The descriptions of the bones and joints, although admirably done from a purely scientific standpoint, must be greatly enlarged and modified before they will come into general use by medical students. Whether topographical anatomy as a separate subject is not a little out of place in this work is a question on which opinions will be divided, but all anatomists will agree that Professor Thane and Mr. Godlee have given us a most accurate and thorough epitome of the relations of the various structures to the surface, which cannot fail to be of great value to the physician and surgeon.

In the second volume more considerable changes have been made than in the first, for in the past six years great advances have taken place in histological and embryological research, and the most important and trustworthy observations have been incorporated in the text. These alterations have been made very judiciously, and have been supplemented by many original investigations by the authors themselves. In the histology of the cell and of the tissues we find the latest views of the editor, Klein, and Flemming, illustrated by many new and beautiful drawings from specimens made by Professor Schäfer himself, whilst the researches of Key and Retzius, Ranvier, Recklinghausen, Ehrlich and other less known microscopists have every attention. Many new drawings from Henle, Schwalbe, and Luschka have been added in illustration of the anatomy of the central nervous system, and so much new matter has been introduced

into this part of the work that it almost seems to be a new treatise. The most important alterations in the chapter on Embryology are due to the researches of His, and particularly to those of the late Professor F. M. Balfour, whose important contributions to this branch of science have considerably modified many of the older teachings on the subject. The value of the monograph on the Development of Elasmobranch Fishes, and of his masterful treatise on Comparative Embryology, can only be correctly estimated when we see the observations and views contained therein at once accepted and acknowledged by the father of embryology in Britain, Dr. Allen Thomson.

The careful and thorough revision, the many improvements, and last, but not least, the bibliography at the end of every section in the second volume, not only again mark out "Quain's Anatomy" as the best work on the subject in the English language, but make it in many respects superior even to such classic works as those of Henle, Cruveilhier, and Sappey. It is now a text-book of which every English anatomist must feel proud.

It is but justice to the publishers to add that they have not failed in performing their share of the task of producing the work. The type is unusually clear and bold, and by extra care in printing many of the old engravings have been almost transformed.

The Student's Guide to Materia Medica and Therapeutics in Accordance with the British Pharmacopœia.

By JOHN C. THOROWGOOD, M.D., F.R.C.P., etc. Second Edition. London: J. & A. Churchill. 1882.

A Medical Formulary Based on the United States and British Pharmacopœias, together with numerous French, German, and Unofficial Preparations. By LAWRENCE JOHNSON, A.M., M.D. London: Sampson Low, Marston, Searle & Rivington. 1882.

Catalogue of the Collections in the Museum of the Pharmaceutical Society of Great Britain. 1878. Compiled by E. M. HOLMES, F.L.S., Curator of the Museum.

WHATEVER satirists may say to the contrary, the value of medicines in the practice of physic is only beginning to be realized. The growing efficiency of chemistry as a hand-maid of medicine, analyzing medicinal substances and separating in minute forms their active principles, and the closer study of the action of medicines, both from a physiological and pathological point of view, have resulted in therapeutical discoveries of the greatest interest and value. To take one instance only, that of the action of pilocarpine, the active principle of *jaborandi*. What action of any of the older diaphoretics will compare in certainty and efficiency with that of pilocarpine, which will produce salivation and diaphoresis within ten or fifteen minutes of its administration? Of course the discovery of such powerful agents involves a corresponding obligation in those who use them to do so intelligently and carefully. Hence the increasing importance of works on *materia medica*, three of which we have named at the head of these remarks, and which, in their several ways, will be found very useful on the table or in the carriage of the practitioner.

Dr. Thorowgood's book has worthily reached a second edition. It assumes a knowledge of, or the means of reference to, the *British Pharmacopœia*. But it explains the principles of the chief pharmaceutical processes employed in making the preparations of the *British Pharmacopœia*. It

would be greatly enhanced by a more complete supplementary notice of drugs which, though not in the British Pharmacopœia, are used by the best practitioners in this or other countries. Unfortunately, the British Pharmacopœia does not at any given time include some of the most valuable preparations and drugs. Notwithstanding this defect, Dr. Thorowgood's book is a most excellent one, not only for students, as he modestly says in the preface, but for practitioners. It gives a clear and concise account of the chemical and pharmaceutical bearings of a drug. But the therapeutical part of the book is also admirably executed. It indicates the personal opinion and experience of the author, in a way not fanciful and far-fetched, but judical and practical.

The work of Dr. Lawrence Johnson, of New York, has a plan larger than, and different from, Dr. Thorowgood's. It aims at giving the drugs and preparations in common use, and includes those of all the Continental, British, and the United States Pharmacopœias. It seeks too to give not merely pharmacopœial preparations, but formularies from leading hospitals and practitioners. It is weak in the statement of therapeutical doctrine and experience, but is nevertheless a work of very great convenience, and one implying much labor and trouble on the part of the author.

The Catalogue of the Collections in the Pharmaceutical Society of Great Britain is a collection which every practitioner would do well to take an opportunity of seeing whenever it presents itself. It is useless for a practitioner to attempt to keep pace with the rapid achievements of organic chemistry and advanced pharmacy. Every week discovers a new alkaloid or a new preparation. But there is no place where an inquiring practitioner can spend a more profitable half hour than in the museum of the Pharmaceutical Society, where he is not unlikely to have at once his pleasure and his knowledge enhanced by meeting Mr. Holmes, the author of the very valuable catalogue under notice, which we may hope soon to see superseded by a new edition.

Diseases of Women. By ARTHUR W. EDIS, M.D. Second Edition. London: Smith, Elder & Co. 1882.

When so fully reviewed the first edition of this work that we shall content ourselves with a few remarks on the second edition. Of the errors which we pointed out many have been corrected, but some retained. For instance, our author adheres as tenaciously to the pathological view of "glairy cervical mucous like white of egg" as this clings to the place of its birth. This is an accurate description of the normal and healthy secretion of the cervix, which may, indeed, be associated with other pathological conditions, but shows that, whatever else is wrong, the secreting apparatus of the cervix is right. The retention of such an error as this must result in the unnecessary and prolonged treatment of numbers of healthy women, and it is in our opinion as easy and as rational to cure this condition as it would be to put a stop to the secretion of gastric juice by the stomach or saliva from the mouth. We are not sure how far the actual words of the description are answerable. "Glairy" is a mysterious and ill-sounding word, and "glairy tenacious discharge" sounds terrible indeed. What woman could live comfortably with a "glairy tenacious discharge" from her uterus? Although Dr. Edis has become decidedly less heroic in his second edition, we think that the mention of any operation endangering life should include a careful definition of the objects in view,

the risks run, the prospects of success, and the indications calling for, or at least justifying, the procedure. Such an operation as division of the cervix should surely not be left as a "something to be done." In treating the subject of Sterility, Dr. Edis recommends (p. 478) the preliminary elimination of male incompetence. Is the examination necessary for ascertaining this, then, to become a practice with "the student and junior practitioner"—to whom the work is addressed—whatever may be Dr. Edis's custom in such cases? It remains to say that the second edition has in no way changed the opinion we formed of the first.

Ogilvie's Imperial Dictionary of the English Language. Edited by CHARLES ANNANDALE, M.A. London and Edinburgh: Blackie & Son.

THE amount of information contained in the older editions of this work has rendered it invaluable to English-speaking peoples for the last quarter of a century, and we cordially welcome this, the latest edition, and predict for it a large and well-deserved sale. Enriched as it is by the addition of new quotations illustrative of the various changes a word may undergo, and the shades of meaning it may possess, it may be regarded not solely as a mere dictionary, as that word is commonly understood, but as a valuable addition to the English encyclopædic literature of 1882. We note with special pleasure the correct and clear meanings that are given to scientific words—medical, chemical, zoological, etc.; and can well understand the pains and trouble that have been taken in these various departments; the woodcuts are numerous and admirably executed; the classical quotations and derivations with which the work abounds are extremely appropriate to a dictionary of a language which is indebted for words to so many different sources as is the English language. Printed in clear legible type, on good paper, and bound in a solid and useful form, this book fully merits the name "imperial,"—a word which is defined in it, amongst other meanings, as "anything of unusual excellence." It is one of the few works of its kind that we are able to speak of in terms of high commendation, and we feel that Mr. Chas. Annandale and his coadjutors deserve praise for their labors, which, it is stated, have extended over ten years.

Animal Plagues; their History, Nature, and Prevention. By GEORGE FLEMING, F.R.C.V.S., F.R.C.S., etc. Vol. 2. London: Baillière, Tindall & Co.

PREVIOUSLY to the outbreak of cattle plague in this country, the history of animal plagues had not attracted much attention, and when the ravages of the malady forced veterinarians and stock-owners into a state of unaccustomed activity, it did not seem to occur to those who were most concerned that the disease was not a new one in veterinary medicine, and for some time England presented the remarkable spectacle of a people seeking with much effort and by circuitous paths information which was lying ready to hand, or at least to eye, in the veterinary literature of Germany and Austria. Had the history of the cattle plague been familiar to English stock-owners in 1865, the saving to agriculture would have been immense, but at that time there was no accessible English work which gave any useful information on the subject, and our farmers, even if they had known anything of the distinguished continental authors who could have enlightened them, are somewhat prone to depreciate the benefits of foreign imports.

It is difficult to convey an adequate idea of the

scope and objects of the work on Animal Plagues without entering further into details than our space will permit, but there need be no hesitation in asserting that the two volumes on Animal Plagues, added to the companion volumes on Veterinary Sanitary Science and Police, and Rabies and Hydrophobia, are evidence of the remarkable industry by the aid of which their author has surmounted difficulties of no ordinary character.

The volume now before us is, we are told, the finish of the writer's labors in this direction. In the first volume, which was published in 1871, the history of epizootics, and incidentally of epidemics, included the period from B.C. 1490 to A.D. 1800. In the present volume the history is continued from 1800 to 1844, after which date the writer remarks, it is not his present intention to carry on the record, as from that time "Veterinary literature became largely developed, and there is no difficulty in tracing the origin and extension of the more remarkable at least of the animal plagues which visited the civilized world." Nevertheless to present in one view a record of the principal epizootics which have appeared since 1844 would be a satisfactory conclusion to the work; and although it might present no difficulty to Mr. Fleming, we question if any of his professional brethren are likely to attempt it.

In carrying out his self-imposed task, the author has adopted the system of chronological reference, instead of attempting a complete history of each form of disease. Commencing in the first volume with the murrains of Egypt, in the first chapter he gives an account, necessarily a concise one, of the plagues which the earliest historians have alluded to between 1490 B.C. and 400 A.D. Then, in the next chapter, in the space of some ninety pages, is compressed the history of eleven hundred years—from A.D. 400 to A.D. 1500—an unprofitable period, as the writer describes it.

Coming gradually to more modern times the accounts of epizootics in various parts of the world become the more interesting, for the reason that it is possible to connect the animal plagues of a former period with those which are familiar to this generation of stock-owners. As a concise record of the rise and progress of animal plagues from the earliest times, the value of the work to the veterinarian cannot be over-stated, and it may not be out of place to suggest that the agriculturist will find in it matter well worthy of his attention. In the last twenty years the stern logic of facts has convinced farmers that the ravages of the most deadly diseases of the lower animals are not, in their outcome, to be lightly estimated; and they are not now disposed to laugh, as they did in 1869, at the idea of legislating for the movement of animals merely because they had a few blisters on their tongues and feet. Mr. Fleming's work is likely to find readers among a class to whom a few years ago its teachings would have seemed to possess no meaning.

The Practical Working of Direct Vaccination from the Calf. By BENJAMIN BROWNING, M.D. Reprinted from the Transactions of the Society of Medical Officers of Health.

IF Dr. Browning had contented himself with giving some account of the methods to which he had resorted for the vaccination of calves, his pamphlet would have merited more approval than we are now able to accord to it. The earlier pages are devoted to an attempt to show that calf lymph should be employed to the exclusion of humanized lymph. A few words will suffice to demonstrate the error into which he has fallen. He begins by showing that absolute immunity from small-pox

is not always to be procured by the use of humanized lymph, and he then makes the bold assertion, that animal lymph "never fails in preventing small-pox." This last statement appears to be based upon the fact that 150 persons vaccinated by him with calf lymph, though living in infected localities, had not subsequently suffered from small-pox. As matter of fact, there is no definite evidence of the amount of protection relatively afforded by humanized and animal lymph, but the history of small-pox hospitals gives ample proof that those exposed to the disease can be efficiently protected by the use of humanized lymph. Again, Dr. Browning states that the success attained in the use of the lymph which he cultivated was 97·13 per cent., but no information is given whether he refers to the number of individuals vaccinated, or to the number of insertions made; probably the former is intended, but there is again no evidence to show what he means by success, or whether he applies this word to cases in which vesicles are developed on only a proportion of the places of insertion. That good results are attained by direct vaccination from the calf there is no doubt, and the report which we recently published on the Animal Vaccine Establishment of the Local Government Board is sufficient evidence on this point; but Dr. Browning's pamphlet is calculated to give rise to the erroneous impression that the use of stored animal lymph is to be entirely trusted to, a belief which should not be encouraged.

We feel, however, with Dr. Browning, that there is ample room for the development of calf vaccination, and although we cannot agree with all the observations which he makes, with reference to the methods to be adopted, some are deserving of attention.

Medical Annotations.

"Ne quid nimis."

PASTEUR'S RESEARCHES.

A LETTER was read at a recent meeting of the Académie des Sciences from M. Pasteur, giving an account of his progress in some researches in which he is at present engaged in the district of Vaucluse. He has gone there to investigate a disease of pigs, which, in one valley of the Rhone, has recently been fatal to 20,000. The disease is called "le rouge des porcs;" and M. Pasteur announces that he has discovered its cause to be a very minute organism, which in point of size resembles that of chicken cholera. It differs, however, in its physiological properties, since it has no action on fowls, but it is fatal to rabbits and pigs, especially to white pigs. M. Pasteur has convinced himself, by experiments, that one attack affords protection against another, and he has succeeded in inoculating pigs with organisms which have been weakened by culture, and in thus rendering these animals insusceptible.

THE CONTAGIOUS DISEASES ACTS AT DEVONPORT.

At the annual meeting of the subscribers to the Royal Albert Hospital at Devonport, which has been recently held, many statements were made in regard to the working and efficiency of the Contagious Diseases Acts, of sufficient weight and importance to give them more than a local interest. The report of the Select Committee of the House of Commons has materially strengthened the hands of the supporters of these Acts, and that this is recognized by their antagonists is im-

mediately apparent. Tracts and addresses have been circulated in Plymouth, Devonport, and Stonehouse, urging that the report is one-sided and not in strict accord with the evidence laid before the Committee. It is therefore of the utmost importance that we should have laid before us the views of those inhabitants in the Three Towns who subscribe to and support the local hospital in which the patients are detained who are under these Acts, as well as the views of the chief naval authorities in charge of the Government establishment at Devonport. These are most explicitly stated in the report of the Hospital Committee and the speeches of Mr. Edward St. Aubyn, its chairman, Mr. J. May, a former mayor of Devonport, Admiral Sir Houston Stewart, K.C.B., and the other admirals and civilians who were present at the annual meeting. The opponents of the Acts now endeavor to show in a most characteristic and ingenious manner that they are unnecessary in that district. Before the Select Committee Inspector Anniss had given perhaps the strongest and most convincing proofs of their efficiency that had been laid before the committee. He showed the value of these Acts not only directly so far as the diminution of venereal disease is concerned, but also in their deterrent and reformatory effects, which Mr. Stansfeld and his supporters so persistently urge as being beyond the scope of, and altogether apart from, their necessary operation. The Watch Committee of the Devonport Council, evidently jealous of the activity of the special inspector, claim that sufficient importance has not been given to the labors of their own superintendent. So that instead of allowing that at any rate much good had been done, the supporters of the opposition to the Contagious Diseases Acts are actually trying to make capital out of petty local rivalries, in which the only dispute is as to whom the credit of the present condition, of the Three Towns is due. If the only object and effect of the Acts is to perpetuate, extend, and render safe the immorality of the districts under the Acts, why should they not at once confess that their estimate of their value in the Plymouth district is at direct variance with the local one? We should then have no difficulty in forming our own conclusions as to which is the more likely to be the correct estimate? During the past year the number of patients in the lock wards has greatly diminished, and at the end of November there were only twenty-eight patients in the hospital. This is the smallest number since the introduction of the Acts, and can it be seriously urged that this does not show that they have been most effectual in dealing with the disease, against whose spread they were especially introduced? Sir Houston Stewart's remarks on the efficiency of similar measures at Malta are very important, for it is continually stated and restated that such restrictions have always been found, in the foreign ports in which they are in operation, ineffectual against the spread of syphilis; and evidence on this point is rarely of such cogency and force as the statement we quote from the worthy admiral's speech:—

"The President, after having thanked the meeting for the compliment paid him, said: 'With regard to the Contagious Diseases Acts I should like to say a few more words. Some years ago I commanded a vessel in the Mediterranean which had a crew of 1350 men. It is the custom on that station for the fleet to winter for six months at Malta, and then be ready to go to sea. I am now speaking of my own vessel, not others of the squadron. During the six months we lay in Malta harbor the Acts were in force, and when the cruising season came round my ship was able to go to sea without any venereal cases. During the absence of the

fleet from Malta some influence prevailed with the then Governor, and the Acts were suspended. Well, the ships returned to Malta and wintered there under the altered circumstances, and in my ship alone when the cruising season came round again we were obliged to leave thirty men behind suffering from disease. You know what that means—three or four guns unmanned, besides other things which had to be neglected. The then Commander-in-Chief in the Mediterranean, and who has since been Commander-in-Chief at Devonport—I mean Sir W. F. Martin—took the subject up. The Governor was a man of sense and judgment, the Acts were put in force again, and with what result? The following winter we again went to Malta, and were able to go to sea in my ship at the end of six months without any cases of disease.'"

HOMŒOPATHY AT THE ANTIPODES.

THE Tasmanian papers contain interesting accounts of the fate of a petition to the Board of the Hospital of Hobart Town, said to be signed by 1,700 people, to set apart a ward for the treatment of cases under the homœopathic system. It should be stated that the Board consists of thirteen laymen and four medical officers. Mr. Dodwell asked the chairman for a return of the number of persons admitted into the hospital who had wished to be treated homœopathically. The chairman said that no such application had ever been made. In the discussion of this question Lord Beaconsfield's case naturally turned up, with disastrous results to the homœopathic argument. The usual statistics showing almost the entire abolition of mortality from fatal diseases under homœopathy were trotted out, but without effect. The medical officers of the Board showed easily that such a system would not conduce to the harmony or efficiency of the hospital, and the Board unanimously negatived the proposal. Even the gentleman who brought it forward voted heartily with the majority. When will homœopaths see the necessity to abolish their shibboleth? As regards their statistics they deceive no one, as comparing homœopathy with an old system of practice as exploded as itself. Nobody with ague would be persuaded by a whole cartload of such statistics to forego the use of good doses of quinine. One set of well-recorded cases of pneumonia, like Dr. Bennett's, without a death, exceeds all the statistics they can bring, even if the question were one of statistics, as it is not.

CHRISTMAS FESTIVITIES.

Few people of middle age view with equanimity the festivities the present season brings with it. This often makes them unjust to those who at the extreme of life are able to enjoy the good things if only indulged in with moderation. Middle-aged prejudice is unusually severe against plum-pudding; yet this article is a highly efficient food, yielding a force equivalent to 250 foot tons. It is also an admirable vehicle for the administration of fat, an article of diet as a rule usually objected to by children. Plum-pudding, in reasonable quantity, is certainly to be preferred to the so-called "wholesome" cakes, which have little fatty matter in their composition. A good wedge of cold plum-pudding is not an unwholesome lunch for young and growing lads to put in their pockets when out for a day's skating or hunting. Elderly people, too, are often able to compete with the younger members of the family in the enjoyment of Christmas cheer in a manner that amazes and discourages their middle-aged relations. The fact is, as has been happily pointed out by Professor

Michael Foster, the digestive elements are long preserved, so that a man who in the prime of manhood was a martyr to dyspepsia, by reason of the sensitiveness of his gastric nerves, in his later years, when his nerves are blunted, and when therefore his peptic cells are able to pursue their chemical work undisturbed by nervous worries, eats and drinks with the courage and success of a boy.

A NEW DEODORIZER.

A STATEMENT was recently made at a meeting of the Burslem Town Council by Dr. Oldham that smoke is really a guardian angel, and instead of a nuisance is really a blessing in disguise. Dr. Oldham contended that the smoke from the factories of his district, blending with the atmosphere, acts as a deodorizer, and thus counteracts the evil effects of bad drainage. The theory that there is virtue in smoke possesses, perhaps, the proverbial two grains of truth hidden in the bushel of chaff. The deodorizing properties of charcoal are well known. It has a wonderful affinity for, and destructive power over, noxious gases. A small handful enclosed in a respirator and placed across the nostrils makes imperceptible to the most delicate olfactory nerve the strongest of odors. The question is, To what extent does coal, smoke, or soot possess the deodorizing and air-purifying properties of charcoal? The healthiness of London, compared with other large towns, is well known, and the fact that it is one of the smokiest inhabited spots on the earth's surface is admitted by all; and the question again arises, Is there any connection between these two facts? If the smoke nuisance has to be tolerated to cure the effluvia of drains, we should, however, prefer attention being paid to the old motto that "prevention is better than cure."

HYDROPHOBIA.

A CASE of death from hydrophobia has been reported from Rochdale. According to the report of the inquest contained in the *Leeds Mercury*, it appears that in June last a dog ran into a shoemaker's shop in Rochdale, and lay down; the owner of the shop went to stroke it, on which the animal bit him in the hand. On Nov. 24th the man presented the first symptoms of hydrophobia—some spasm on an attempt to drink. By the advice of a medical man, he took a vapor bath, and seemed to be better. Apparently growing worse, he was taken, on Nov. 27th, to the workhouse, and there was "seized, and his arms strapped," treatment which his son declared was "barbarous." The chief attendant in the "imbecile ward," states that on admission the patient "was very violent, and became insensible at times. Dr. Pinck, the surgeon, ordered him to be put into a padded room. He was accordingly put to bed, and some medicine was administered, and two inmates were directed to attend to him." He died at eight o'clock the following morning. The coroner expressed the opinion that the patient's arms ought not to have been strapped. It is not easy to form just opinion of the treatment of such a case without further details than the report affords, but it certainly does not seem to have been very satisfactory, although we are scarcely inclined to apportion the blame in the same way as the coroner. In the later stages of hydrophobia there is often considerable maniacal violence, rendering some mechanical restraint inevitable; and if a patient in such a state is taken to a workhouse in the absence of the medical officer, it is natural that the officials, recognizing the necessity of restraint, should apply it in the way they are accustomed to

adopt in violent cases of insanity. But why, we would ask, was the patient taken to the workhouse at all? What could be more calculated to aggravate his excitement than forced removal to such a place, during the stage of the disease in which the mental state is most disturbed? Surely a master shoemaker, living apparently in his own house, could have been treated there during the brief duration of such a disease. The only chance of recovery, infinitesimally small though it be, is afforded by the maintenance of absolute tranquility of mind and body, and its furtherance by sedative treatment. If a case of hydrophobia is removed at all, it should be in the early stage of the disease, before excitement sets in. But if moved, why was such a patient taken to the workhouse? Rochdale, according to the Medical Directory, contains an infirmary and dispensary, with nine beds, four surgeons, and a resident medical officer. What is the use of such an institution if a case of hydrophobia has to be taken to the workhouse?

SIMULATED INSANITY.

A CASE tried the other day at the Toulouse assizes possessed no little pathological interest, as one of the three prisoners, a young man of eight-and-twenty, who was accused of committing a series of thefts from shops, had become insane from having, between the time of his arrest and his trial, simulated madness. When first arrested he made several attempts to escape, but finding that there was no chance of this he fell into a state of lethargy and pretended not to understand what was said to him. Three doctors were commissioned to examine him, but they reported him to be perfectly sane, and he was accordingly put into the dock with his two accomplices. He refused, however, to answer the questions which were put to him, and his counsel stated that though he had at first only pretended to be mad he had finally become so in reality. The Court, without directing the jury to acquit him on the ground of insanity, were so far convinced that such was the case that they adjourned the trial and ordered him to be removed to an asylum, pending a fresh examination of him by a specialist from Montpellier.

THE COMPOSITION OF CERTAIN ORGANIC LIQUIDS.

THE Strongylocentrus lividus (Brandt), belonging to the class of echinoderms, contains in its interior a liquid which is taken by the inhabitants of certain districts in the South of France under the impression that it is a digestive tonic, and it seems to have such an action when taken in the dose of half a wineglass daily. It thus constitutes a sort of animal mineral water. Its composition has been ascertained by MM. Mourson and Schlagdenhauffen. When fresh it is neutral in reaction, but in a few days it becomes turbid, acquires a fetid odor, and deposits brownish flocculi. Its reaction is then alkaline, and it contains ammoniacal and sulphuretted compounds; 1,000 parts of it contain 959 of water, and 41 of solid matters, of which 37 are fixed salts, consisting chiefly of chloride of sodium, with some chloride of magnesium, small quantities of the sulphates of calcium and magnesium, and traces of chloride of potassium, and carbonate of calcium. There are also three parts of organic matters containing fatty matters or ptomaine, a little urea, and a little albuminoid matter. From this analysis the liquid apparently consists of sea-water, with an excess of carbonic acid and nitrogen (as if modified by the products of respiration), excrementitious matters, and some products which are probably derived from the organs of generation. The ptomaine

seemed to have an action on the frog, although the effect was not fatal, because the quantity that could be obtained was insufficient to produce a full toxic condition. It is conjectured that the ptomaine may be the same which is present in some bivalve mollusca, as mussels, and at a certain time of the year causes poisonous effects. The same investigators also analyzed the liquid contained in hydatid cysts and cysticerci. The nutrition of living hydatids must be effected by passage into their interior of the serum of the blood, according to the laws of endosmosis. Analysis showed that clear hydatid liquid does contain a small quantity of albumen, although too little to be revealed by the ordinary method of testing with heat and nitric acid. Moreover, all hydatid liquids contain a variable quantity of a ptomaine, which it is conjectured may be the cause of the toxic effects (urticaria, peritonitis) which have sometimes been observed to follow the irruption of these liquids into one of the serous cavities of the human body. Nevertheless experiments on frogs yielded only a negative result. They seem to be most abundant at the period of evolution of the echinococci, and scanty during the inactive stage, a fact which may explain why the rupture of a cyst is sometimes followed by serious consequences, and sometimes by none. All these liquids are extremely putrescible. The liquid contained in the large vesicle of *cysticercus tenuicollis* contains a relatively considerable amount of albumen, and possesses very marked poisonous properties. The symptoms produced by its inoculation are closely similar to those produced by the inoculation of the poison of certain venomous animals. Injected into the peritoneal cavity of rabbits, it causes their death with all the signs of decomposition of the blood. A distant analogy of the physiological relation and chemical composition of these liquids and that of the liquor amnii led to an examination of the latter also. The investigators succeeded in demonstrating the presence of a ptomaine in this also, obtained at the time of labour by a puncture of the membranes. Its quantity was very small, but their conjecture that if it is ever present in larger amount it may furnish an explanation of some of the accidents of gestation.

FASTING IN ACUTE RHEUMATISM.

DR. CAREY E. WOOD, professor of chemistry in the medical department of Bishop's College, Montreal, in an article in the *Canada Medical Record*, recommends starvation as the treatment of acute rheumatism. He gives a history of seven cases restored to health by simply abstaining from food for from four to eight days. Amongst other advantages of the treatment cardiac complications are almost entirely averted. And he says he could give the history of forty more from his own practice. His patients were allowed to drink freely of lemonade or of cold water. In no case did the treatment fail! He is inclined to think from these cases that rheumatism is only a phase of indigestion, and that by giving complete and continued rest to all the viscera that take part in digestion the disease is attacked in *ipsa radice*. If we mistake not, Dr. Gill, of Canterbury, has anticipated the author as regards his theory of the origin of the disease in disorders of the viscera concerned in digestion. We are quite disposed to think that the rôle of starvation or fasting in therapeutics is far more considerable than has yet been described. It is an old Scripture that "fasting" is half the battle in expelling some devils. But we confess to being not a little sceptical in regard to Dr. Wood's remedy for rheumatic fever—a disease occurring often in subjects of delicate constitution.

Besides the disease itself is most exhausting, being compounded of pain, sweating, and high temperature, and these extending over a long time. While it is our duty to record such statements as Dr. Wood's, it is equally our duty to say that they do not commend themselves to us as embodying the truth either as regards the pathology or the treatment of this remarkable disease, which, till Dr. Mac-lagan's discovery of the power of salicin over it, was an opprobrium to medical science, and which even now in some cases taxes all the resources of the physician.

SCARCITY OF SUBJECTS IN AMERICA.

A REPORT which has reached us from America shows that the scarcity of subjects in our metropolitan and provincial dissecting-rooms, to which we alluded at the beginning of the winter session, has prevailed there too. Philadelphia is just now excited over the capture of a band of grave-robbers, or, as they are better known in this country, resurrectionists, who were caught with six bodies, intended for the medical college in that town, in their possession. An investigation shows that the robbers had almost cleared one of the cemeteries. The recovered corpses have been identified, and the men are now in gaol waiting their trial. The dearth of material for dissecting is a subject that will shortly have to be dealt with, and some alteration be made respecting the present limited supply.

MYOSITIS OSSIFICANS.

At a recent meeting of the Vienna Medical Society Professor Podrazki exhibited a soldier affected with the rare condition which has been termed myositis ossificans. Four weeks previously the man had applied for treatment, on account of an intense inflammation of the muscles on the front of the right upper arm, apparently set up by severe gymnastic exercise. The muscles were large, hard and uneven, and the elbow-joint was fixed in flexion. The hardness was removed, and some increased mobility was obtained, by massage and the application of cold. At the end of two weeks a hard, round, movable tumour developed in the flexor of the elbow, which was evidently due to an ossification of the brachialis anticus. At first it was movable, the upper part appeared to be cartilaginous, and it was evidently not connected with the periosteum. Podrazki has seen, in the course of nineteen years, two cases in the practice of Pitha quite similar to this in their characters. In those two cases neither iodide of potassium, nor any other treatment adopted, had any influence. In a discussion which followed, Professor Wein-lechner stated that he had twice seen similar small spots of ossification in the muscles on the front of the leg, due, in each case, to a traumatic cause. Kundrat expressed the opinion that some supposed exostoses on the thigh proceed from muscles. Their form and seat correspond to certain muscles. Their greater frequency in men, and especially in muscular individuals, suggest that their origin is traumatic. They constantly become adherent to bone in the course of their growth, and hence are commonly thought to be primary exostoses.

VASCULAR DILATATION.

THE mechanism of dilatation of the vessels has for a long time occupied the attention of MM. Dastre and Morat. Previous researches have led them to conclude that the sympathetic is a mixed system of nerves, containing fibres which dilate as well as those which constrict the vessels. The investigators have shown that this is true of the vaso-

motor fibres for the neck, face, ear, and limbs. This principal point having been established, it becomes easy to follow the course of the nervous excitations, which, proceeding from certain parts of the sensory apparatus, provoke reflex dilatation of the vessels in various parts of the organism—a course which includes, necessarily, centripetal fibres, a centre, and the efferent fibres contained in the sympathetic. As a type of the reflex, they have recently studied that which is known as the auricular reflex, or Snellen's reflex; and their results have been communicated to the Académie des Sciences. The principal sensory nerve of the ear is the great auricular, a branch of the cervical plexus. Sensory impressions on the external ear are by this nerve conducted to the spinal cord by the second or third cervical roots. If the nerve is divided and its central end stimulated, reflex congestion of the ear is produced, which is sometimes enormous in amount. This vascular dilatation is preceded by a slight constriction if the exciting current is of moderate intensity; but if the current is strong the dilatation occurs at once. The effect is produced by the mechanism of the vaso-dilator nerves which come from the spinal cord by the eighth cervical and first two dorsal pairs, and which pass thence into the sympathetic. In order to ascertain the whole of the course traversed by the excitation, it is only necessary to find its path in the spinal cord. For this purpose MM. Dastre and Morat have made the following experiments. In a white rabbit the spinal cord was divided unilaterally, somewhere between the third and seventh cervical pairs. The operation was followed by a bright congestion of the whole head, especially of the ear, on the corresponding side. The congestion disappeared at the end of a few hours; it must therefore be ascribed to an excitation, and not to a paralysis. When the circulation had become normal the two auriculo-cervical nerves were divided and then the central extremities were stimulated. On the normal side reflex congestion at once resulted; but on the side operated on no effect was produced. The operation was also performed in another manner. Instead of a hemisection, the cord was divided entirely, artificial respiration being maintained. After one or two hours, when the congestion from the operation had disappeared, the auriculo-cervical nerve on each side was stimulated, but no effect was produced. The conclusion is, that the interruption to the continuity of the cervical cord between the second and eighth cervical pairs abolishes the vaso-dilator reflex of the ear. The integrity of this spinal segment is therefore a necessary condition for the phenomenon. A division of the cord below the sixth dorsal has no effect on the reflex.

"OVERLAIN."

THE *Sussex Daily News* of Dec. 28th records another name to be added to the ghastly roll of children suffocated in bed, or, to use a well known and too familiar expression, of children overlaid. The mother at the inquest deposed that she took the child, aged four months, to bed with her about half-past eleven. She fed it about two o'clock, and waking up again at twenty minutes to six found the child dead. It was lying under her left arm. She and her husband and two children slept in one bed. Dr. Arthur, who was called in when the child was discovered to be dead, in the course of his evidence very properly expressed a wish to direct public attention once more to the great sacrifice of infantile life in the country caused by children being overlaid. He suggested that when it was not possible for the parents to obtain a crib or bassinette for a child, they should get an

orange-box, which could almost always be had for the asking. The substitute recommended by Dr. Arthur is a perfectly suitable one, and his remarks are practical. We fear that many an infant holds its life by a feeble thread. If its parents have "a good night," all is well; but if they have exceeded the bounds of moderation in eating and drinking, or are unfortunately troubled with nightmare and dreams which cause restlessness, the life of the infant is imperilled and often sacrificed. No doubt in many cases genuine sorrow is felt, and contrite tears are shed, but the evil still continues to be a reproach to our nineteenth century humanity and civilization.

THE ADMINISTRATION OF CHLOROFORM TO CHILDREN.

We regret the fatal case of chloroform administration which has recently occurred at the Children's Hospital, Great Ormond-street. The facts are as follows:—A little girl, aged five years, was suffering from disease of the knee-joint, and an abscess in connection therewith required to be opened. According to the newspaper report, "but little chloroform had been administered—enough to dull sensibility," and after the necessary incision had been made, the duration of which was only momentary, it was found that the heart had ceased to beat. Artificial respiration was at once adopted, but without avail. A post-mortem examination, which was made by Mr. Pepper, revealed nothing special, and death was considered to be due to "syncope produced by the influence of chloroform." The coroner's jury seems to have taken a reasonable view of the case, only appending to their verdict the suggestion that, if practicable, parents should be informed when it was proposed to give their children chloroform. We are far from wishing to minimize the importance of this accident, infinitely rare as it must be admitted to be. In no branch of practice has the use of chloroform been more precious than in that of children's diseases—alike in saving the patient from terror and actual suffering, in rendering the surgeon important aid, and, it must be added, not unfrequently in assisting the physician in various methods of diagnosis. So widespread has been the confidence in the safety of this anæsthetic for children, and so much more manageable has it been found than ether, that in children's practice the employment of chloroform has scarcely been challenged. But this accident ought to induce all who have to give anæsthetics to seriously reconsider Mr. Warrington Haward's valuable experiences on Ether Administration, published years ago, many of which, it may be added, referred to children. Without venturing on any special criticism of the Children's Hospital case, we may state our strong conviction of the importance of two points in chloroform administration alike in children and adults—(1) That the risk of cardiac failure is diminished by giving a small quantity of alcohol a short time before the chloroform; and (2) that when any operation, however slight, is contemplated, complete is far safer than partial anæsthesia, in which the reflexes are only blunted.

CHLORAL-POISONING.

At an inquest on the body of a lady who had died from the effects of an overdose of chloral, a juryman innocently remarked that the bottle which had contained "the chloral was not labelled 'poison' as he thought it ought to be." Chloral is not classed as *poison*. It is one of the most dangerous, because insidious, of poisons; but, unhappily, the law—and we regret to say some members of the medical profession—do not so re-

gard it. Because in certain small doses chloral or chloral hydrate produces a slightly comatose condition which burlesques sleep, and which those who are ignorant of the real nature of "physiological rest" mistake for sleep, the public are permitted to employ, and medical men do not scruple to recommend, these pernicious poisons as though they were innocuous. It is high time that attention were directed to the subject of "narcotics" generally, and the use of chloral and bromide of potassium in particular. Incalculable injury is being done, and public opinion is being grievously misled by the tolerance given to the use of "sleeping draughts," *falsely so-called*. In regard to this matter and that of the reckless use of hypodermic injections of morphia, the profession should seek to form a deliberate judgment and gravely deliver itself. At the present moment we lie under a heavy responsibility, which it is idle to deny and vain to disown.

POTTED PUTRESCENCE.

In addition to the perils which lurk in the pot and its accessories in connection with "potted meats," we are now being brought face to face with another source of danger and annoyance. It seems that the meat itself is too often putrid, or very nearly so, before it is preserved. In fact, if we are to accept the obvious inference from recent revelations in the potted meat and sausage trade, it must be recognized that the preparation of food by mincing and "preserving" offers special facilities for the disposal of material which would otherwise be useless on account of commencing decomposition. The matter is so serious that it becomes a question of expediency whether, looking to the knavish practices to which unscrupulous tradesmen resort, it is safe to use a preparation which, for aught the consumer can tell, may have been compounded of foul and poisonous substances with which he would not feed the dogs in his kennel. If the public would be safe potted meats must be eschewed altogether. The admixture of spices and the general treatment of the flesh reduced to the consistency of paste, render it impracticable for any unskilled person to determine whether what he has purchased is fit for food, and as tradesmen are not to be trusted it would perhaps be better to forego the use of potted meats altogether.

THE FUNCTION OF THE PANCREAS IN FEVER.

DR. STOLNIKOW, of St. Petersburg, gives, in a communication to Virchow's *Archiv*, the results of his observations on the changes in the activity of the pancreas in fever. He refers, in the first place, to the well-known disturbances of the digestive organs that accompany and characterize febrile states of the system; to the thirst, dryness of tongue, nausea, loss of appetite, and abdominal pain; to the changes in the salivary secretion observed by Mosler, such as the deficiency in its quantity, its acid reaction, the absence of sulphocyanide of potassium and of the diastatic ferment, so that it is incapable of converting starch into sugar; and again to the changes observed by Manassein in the gastric juice, which, like the saliva, is diminished in quantity, and so altered in properties that it cannot exert its proper digestive power. But he says few or no attempts have been made to trace the changes occurring in the pancreas and its secretion, though there are good *a priori* grounds for believing that corresponding changes would occur. As the pancreas secretes a fluid containing powerful diastatic and fat-dissintegrating ferments, as well as a ferment acting on albumen, the inquiry has a special interest for

Russian physicians, since many of the inhabitants of the more remote provinces are chiefly fed on starches and fats. In his experiments he first made a pancreatic fistula in accordance with the directions in Cyon's "Methodik," and after ascertaining the normal mode and kind of secretion, he injected purilage into the dog on which the investigation was made. The result was that the quantity of the pancreatic secretion was at first augmented to a considerable extent, the rise being from 2-3 ccm. per hour to 70-79 ccm. per hour. This effect was brief, and was followed by diminution, and when the quantity had diminished the increase usually observed after the ingestion of food failed to occur. The cause of the increase in quantity he considers to be excitation of the secretory nerves of the gland by the septic poison; its subsequent arrest he attributes to the paralysis of the nerves, the septic poison in fact acting in the same manner that atropia does on the nerves of the salivary glands. In regard to the quantity of the special ferments contained in the pancreatic juice, they also would appear to be at first augmented and then diminished, the diminution being occasioned by the depressing influence exerted by the septic poison both upon the trophic nerves and upon the cells themselves, in which pathological processes are established. The influence of the fever in producing a persistent depressing effect is greatly in excess in its duration over its exciting effect, and hence he considers that the employment of pilocarpine in fever has a logical foundation.

EPIDEMIC OF SORE-THROAT.

An epidemic of sore-throat has been prevalent in the neighborhood of Kingston and Surbiton, and the anxiety caused by it is increased by the circumstance that its exact nature and origin are not as yet clear. From the imperfect information available, it would appear that the disease exhibits less of an infectious character than is usually the case when diphtheria is prevalent. But still the number of persons who have suffered is considerable. In 1880, some fifty cases and ten deaths from diphtheria were traced to an infected milk supply in Surbiton; but the district was singularly free from the disease in 1881. Although infected milk is suspected to have borne, at least, a share in the production of the present outbreak, no definite information as to this is as yet forthcoming.

MORTALITY FROM SNAKE-BITES IN INDIA.

SIR JOSEPH FAYRE contributes to *Nature* for Dec. 28th an article on this subject, to which, as is well known, he has devoted much attention, and that with great benefit to the natives and residents of India. As a result of the representations of Sir Joseph the Government have published a resolution which seems to indicate the carrying out of an organized scheme for the destruction of venomous snakes in the Dependency. And it is time that this matter should be taken up with intelligence and determination, seeing that in 1881 18,910 human beings fell victims to snake-bite. "For the purpose of destroying the reptiles it is absolutely necessary that a fixed system of rewards should be established," says Sir Joseph. These rewards, it would appear, have been given too indiscriminately, not sufficient care having been taken to ensure that the snakes killed were really of a venomous kind. Some improvement has, however, taken place both in the number of snakes destroyed and in the cost at which the extermination was effected. Thus in 1880 212,776 snakes were killed at a cost of 11,663 rupees, whilst in

the following year an expenditure of 11,961 rupees was accompanied by the destruction of 254,968 of the venomous tribe.

Correspondence.

"Audi alteram partem."

THE DETECTION OF THE TUBERCLE BACILLUS.

To the Editor of THE LANCET.

SIR—In your last issue you publish a long and somewhat incoherent letter from Dr. G. A. Heron, in which he impugns the veracity of my statements with regard to the new stain I have brought out for the bacillus of tubercle. Most of the objections raised in his letter were mentioned by him at the Medical Society's meeting, on the 4th of December, and refuted by me to the entire satisfaction, I think, of all present, saving of course Dr. Heron. He has, however, now done me the honor to review the various papers I have published on this subject, and to draw from them deductions not at all flattering to my truthfulness. I cannot allow these to pass without remark. Immediately after the meeting of the Medical Society, Dr. Heron appears to have called on Mr. Beck, the agent or salesman of the Badesche Anilin Fabrik, and he gives the result of his interview. On referring to the price list of this company I find that they do not quote fuchsin in it; what then could they do when a customer asked for fuchsin, but sell him the nearest thing they had to it? Does this, however, prove that fuchsin and magenta are the same? As to the use of these names on the Continent I can say nothing, but that they are used in the trade here to signify the same thing is not correct. Let Dr. Heron refer to the price lists of Messrs. Hopkins & Williams, Messrs. Jackson & Co., and Messrs. Becker & Co. He will there find magenta and fuchsin both quoted, the one (fuchsin) at double the price of the other. Does Dr. Heron suppose that firms of this standing are trying to defraud the public by selling the same substance under two names, and charging in the one case double what they do in the other? Dr. Heron admits in his letter that he knows nothing of the chemistry of the anilin compounds. He is therefore probably unaware that magenta is a very comprehensive term, and includes the hydrochloride, acetate, nitrate and sulphate of rosanilin. Does Dr. Heron think that all these will stain the tubercle bacillus? If so I would advise him to make some original investigations into the subject; he will then be able to speak with some authority on the matter.

The facts of the case are these: When Ehrlich's method was first published he mentioned fuchsin as the stain used, as well as methyl violet and gentian violet. By this fuchsin I understood the fuchsin sold by Messrs. Hopkins & Williams, and Messrs. Becker & Co., and which I had used for a very long time for various staining purposes. I therefore made the stain by the method given, and tried it. I certainly could see the bacilli, which I never could do by Koch's method. But they soon faded, which was exactly Dr. Heron's experience, vide *British Medical Journal*, Oct. 14th. p. 735, where he says: "These anilin dyes are apt to fade very quickly; they may illustrate markedly the presence of the tubercle bacilli at the first examination of a prepared specimen, and within twelve hours there may not be one of the organ-

isms visible." Upon this I determined to try to find a better method, and for this purpose I made a very large number of experiments and at last succeeded in making a stain which will not fade and is easily used—applying the anilin oil to make a definite compound and not for the sake of its alkalinity, as Ehrlich did; using, also, a rosanilin salt and not fuchsin, which is, I believe, a by-product in the manufacture of rosanilin. Dr. Heron says in his letter, "I have repeatedly examined the bacillus under an ordinary $\frac{1}{4}$ in. object glass, and with very ordinary London daylight as my only illumination."

In his account of Ehrlich's method, published in the *British Medical Journal*, October 14th, page 735, he says, "a power of 500 diameters is sufficient." If Dr. Heron is now using the same stain he did in August how does he account for this difference of opinion, that in August, he advised a 1-10 in. object glass to "easily verify" that which he can now see with a $\frac{1}{4}$ in.? At the Worcester meeting he told me he could see the bacilli with a $\frac{1}{4}$ in., but that he required special illumination. If the specimens he made then were so easily shown why did he not exhibit some at the Worcester meeting? In his account of Ehrlich's process in the above-mentioned paper he states, "In the specimens I prepared in this way before the section of pathology at Worcester, the bacilli were seen in large numbers." By whom were they seen? When I left the room everything was over, and there were only a few people there, and from the time the section opened in the morning until I went away, Dr. Heron had not shown a single specimen under the microscope. I exhibited there two specimens of the bacilli in sputum under precisely similar conditions. The one prepared by myself, the other after Ehrlich's method by one of Dr. Koch's assistants. In mine the bacilli were very plain, in the other not one was to be seen. The power used was one of Messrs. R. & J. Becks 1-6", economic series. In the Ehrlich specimen they could be seen by artificial light. For the rows of bead-like bodies I would refer Dr. Heron to Mr. E. M. Nelson's drawing published in the *English Mechanic*.

In giving me a description of some preparations I sent him for examination, Mr. E. M. Nelson (who exhibited the specimens sent over by Dr. Koch to Mr. Cheyne at the various societies) says, "they are by far the finest specimens I have ever seen. The slide of sputum under a 1-25 N. A. 1.38 is a picture indeed. I could see the bacilli in that slide with a 2-3 and A eyepiece, with a $\frac{1}{4}$ inch of 40" and A eyepiece they were readily seen. Could bead them with a $\frac{1}{4}$ of 95."

Dr. Heron admits that his specimens have faded; now mine have not, and those I showed at Worcester are as bright as ever, while two slides that were exposed to the daylight for over three months remained unaltered.

In conclusion, I would refer to the experience of the large number of men in this country, who after using Ehrlich's method are now using mine.

I am, Sir, very faithfully yours,

HENEAGE GIBBES.

Gower-Street, Dec. 25th, 1882.

SUDDEN DEATH AFTER DIPHTHERIA.

To the Editor of THE LANCET.

SIR—Mr. Percy Pope gives cases of sudden death after diphtheria. I have known three cases of sudden death in India during convalescence from diphtheria. Inman, in one of his books, if I remember rightly, gives cases of similar sudden death during convalescence from certain fevers, and I think his explanation of the phenomenon is

that, as the heart is a muscle, it becomes as weak as any other portion of the muscular system, and being a most important muscle, on the proper action of which life depends, any sudden effort during convalescence which calls upon the heart to make an instantaneous and powerful contraction, finds it unequal to the task, and, as if paralyzed, ceases to act. An emotion such as would cause a sudden outburst of laughter or any exertion on the part of the convalescent might be sufficient to cause the heart to collapse. If this be the case the remedy is a scrupulous care to prevent the convalescent from making the slightest exertion, and to prevent the occurrence of any emotion whatever, and to force him to keep the recumbent position until, by tonics, stimulants, food, and sleep, the muscular system—and with it the heart—acquires tone enough to meet demands on its contractile force.—I am, Sir, yours obediently,

E. BONAVIA, M.D.,

Surgeon-major, Indian Medical Department.
Etawah, India, Nov. 2nd, 1882.

PERMANGANATE OF POTASH PILLS.

To the Editor of THE LANCET.

SIR—Permanganate of potash pills, containing one or two grains of the salt, are recommended by Drs. Ringer and Murrell for amenorrhoea. Having during the last few days heard of cases of their spontaneous combustion, which it is very probable will occur if the common excipient containing glycerine, now generally used by dispensers, be used to mass them, I wish to point out that any readily oxidized excipient should not be used. Having prepared a quantity of the pills, I found the following basis to answer best:—Vaseline, two parts, paraffin wax, one part; melt, stir till cold, and add kaolin, three parts; mix well. This binds the powered permanganate together, and with a little dexterity the pills may be rolled out without much difficulty, and dusted over with kaolin. They may be coated with sandarach dissolved in absolute alcohol, and rendered tasteless. Cocoa butter may be used as an excipient, but it in time reduces the permanganate, and it is troublesome to manipulate. In solution a dose of permanganate of potash is very nauseous; in a tasteless pill, which dissolves slowly and yet can be easily disintegrated, it is, besides, more agreeable to the stomach than in solution.—I am Sir, yours truly,

WM. MARTINDALE.

New Cavendish-street, London, W., Jan. 8th, 1883.

SEWER VENTILATION.

To the Editor of THE LANCET.

SIR—The two great sanitary questions that are employing the attention of medical men at the present time are with regard to (1) the disposal of sewage in our large towns, and (2) the ventilation of the main sewers. As regards the former, it may safely be said that nothing should be thrown away which can really be made use of, and therefore the question resolves itself into which is the better system—irrigation or precipitation. As regards the latter question, I think it may safely be said that closed sewers are bad, inasmuch as the gases generated and various disease germs are likely to find their way even through the traps into the neighboring houses. But there are two ways of ventilating the sewer, i. e.—at the road level, and above the roofs of the houses by means of air shafts.

Those who advocate road gratings say that air is the best antiseptic, and the greater the number of ventilators the purer the air and the greater the

safety. There can be no question, I think, that ventilators tend to lessen the generation and accumulation of sulphuretted hydrogen, and to dilute that already formed; but still they must, at the same time, allow of the egress of various disease germs. Air may be sweet, but it may be dangerous, just as water may look clear and sparkling, and yet be poisonous. The life of germs is at present, I believe, scarcely ascertained, but we know that scarlatina and, it is said, cholera germs, even after long exposure to the air, will, on being subjected to heat and moisture, readily break forth into life, and reproduce themselves. This no doubt, in great measure, accounts for the successive outbreaks of disease. It certainly seems to me that ventilating ground gratings is approaching very closely the old system of open sewers, which was long ago condemned. I know of many places where these road ventilators have been adopted and become a nuisance, and there are no doubt many who could testify to the same fact. The only way to ventilate the sewers so as to prevent their being a nuisance and a source of danger is to run up air-shafts by the sides of the houses above the roof level. When two ways exist of remedying a nuisance, surely it is best to choose the one which involves the less danger. Of this I should say there cannot be a question.

I am, Sir, your obedient servant,

F. P. ATKINSON.

Kingston-on-Thames, Dec. 18th, 1882.

CHARGES AGAINST MEDICAL MEN.

To the Editor of THE LANCET.

SIR—Whatever may be the result of the Hounslow inquiry, the sad circumstances culminating in the suicide of the late Dr. Edwardes very pointedly direct the attention of medical practitioners to the ever present and real danger they are subject to, of charges of immorality or indecency being brought against them by hysterical and erotic female patients. A medical man cannot be too cautious when dealing with young married or unmarried women. When a morbid thought has once seized upon a mind debilitated and weakened by disease, who can answer for the result? A complete and coherent delusion may be created with lightning speed in such hysteria-affected brain, and so convincing may be the apparent chain of evidence, that a recognition of mania might never occur, or, at any rate, not until an unsullied reputation has been irretrievably ruined and undone. Accusations of this kind made by female patients against their medical attendant should always be entertained with the greatest caution, and ought to be very carefully investigated, for I have known conviction in a court of law follow, on more than one occasion, charges which were afterwards found to be entirely baseless and imaginary.

JAMES GREENWOOD, Barrister-at-Law.

January 9th, 1883.

"PERMANGANATE OF POTASH IN GONORRHOEA."

To the Editor of THE LANCET.

SIR—No doubt many of your readers have tried injections of permanganate of potash in gonorrhoea. May I ask, through the medium of your columns, those who have done so to kindly give me their results. For some time past I have prescribed from two to four drachms of Condy's fluid to half a pint of water as an injection, a small syringe being used many times a day in all cases that have come under my treatment, and in

all stages, from acute to old standing gleet, with the result of a cure within a fortnight in every case. The injection is almost painless, and, I believe, altogether harmless, the only other treatment required being abstinence from alcoholic drinks.

I am, Sir, yours faithfully,

T. H. F. TOTHELL, M.R.C.P. Edin., etc.

Colombo, Ceylon, Dec. 7th, 1882.

POST-PARTUM HÆMORRHAGE.

To the Editor of THE LANCET.

SIR—The cases in which the injection of perchloride of iron fails to arrest post-partum hæmorrhage are so comparatively rare that the following particulars may interest your readers.

The patient in question, Mrs. J. O—, was a thin, spare woman, thirty-three years of age. Her general health had always been good. In all her previous confinements there had been considerable difficulty in extracting the placenta. On a previous occasion it had been extracted piecemeal, with subsequent profuse post-partum hæmorrhage, and a tedious recovery. In her last confinement (eighteen months ago) I managed to peel it off entire; good uterine contraction followed, and she recovered well. During her last pregnancy she had been in good health. On December 7th there were irregular back pains, with some discharge of liquor amnii, but labour did not set in until the next day at 3 P.M. The presentation was normal, and in an hour a fair-sized male child was born. The uterus at first contracted well, but in a few minutes it relaxed, and hæmorrhage commenced. Traction on the cord failed, and, knowing her condition by former experience, I introduced my hand into the uterus. I was unable to peel off the placenta entire, and had to extract it piecemeal, an operation that took me three or four minutes. The hæmorrhage was very free, and, as it continued, I introduced a tube into the fundus uteri and injected a stream of warm water. This proceeding caused good uterine contraction, and stayed the bleeding for perhaps twenty minutes. During the next hour the hæmorrhage kept occurring at intervals, despite the use of hot water, ice, ergot, kneading the uterus, etc.; and as her condition was becoming critical, I decided to inject perchloride of iron. Sixteen ounces of the solution (one part solution of perchloride of iron to three parts water) were injected during the next five minutes. This had the effect of apparently checking the hæmorrhage, but no improvement followed, and I found on examination that the uterus (on which no external pressure had been made since the iron injections) and vagina were full of clots the color and consistence of coffee-grounds and syrup. These were cleared away, and the iron injection repeated. The patient, however, became more and more restless, and died of exhaustion at 8 P.M., four hours after the birth of the child, and about two hours and a half after the first application of the iron to the uterus.

It has since occurred to me that post-partum hæmorrhage could be controlled by the following apparatus:—A large, thin, india-rubber bag, mounted (after the manner of the epistaxis apparatus) on a large, hollow, elastic gum-stem, through which it could be rapidly distended with warm water. The stem is to be connected by india-rubber tubing with the bottom of a can of warm water, which could be placed at any level above the patient. The bag, which would require to be of such size as to allow of its filling the uterus, to be introduced in its collapsed state. On connecting

the bag with the can there would be an amount of pressure on the interior of the uterus, which could be regulated at pleasure by raising or lowering the can. It could be made sufficient to check all hæmorrhage, and could be gradually dispensed with as the uterus regains its power of contraction.

I am, Sir, yours, etc.,

ARTHUR B. VANES.

Uitenhage, Cape Colony, Dec. 23rd, 1882.

INTRA-UTERINE FRACTURE.

To the Editor of THE LANCET.

SIR—From the rarity of cases recorded in the medical journals, and from the somewhat scanty notice given in some of our text-books to the subject of intra-uterine fracture, I thought that this case might be of interest to some of your readers.

E. T—, the mother of ten healthy children, was about the 25th of August, 1882, in the seventh month of pregnancy, when her foot caught against a broken piece of toy, and she fell down five steps. She incurred no injury, but was very much frightened. On the 25th of the following October, after a natural labour, she gave birth to a small and delicate child—a boy. Soon after birth the child's right clavicle was seen to be very much deformed. The acromial end forms with the rest of the bone a figure something like a V, with the open end pointing forwards. The whole bone is one piece, and feels quite firm. There is free movement in the shoulder-joint.
